Pirentepe Photographs

Photo 1 View looking north-east of resistive silica cap exposed at two elevations at Celdiren Tepe (higher level) and Dagtarla Tepe (lower elevation) at approximately 481500 E 4421500 N. The offset in elevation is attributed to extensional down-

faulting along the 060 trending corridor of fracturing and brecciation on the southern margin of the Pirentepe prospect.

Photo 2 Bedded dacitic to rhyolitic tuffs in drainages south of Büyükdag Tepe in the central Pirentepe prospect area (approximately 480500 E 4421300 N). These tuffs demonstrate the sub aerial deposition of eruptive products from a volcanic centre. The high primary porosity of these units enabled siliceous fluids to permeate and silicify these tuffs preferentially. This early silicification event was a precursor to later 060 trending fracturing and brecciation, and mineralisation (e.g. at Davulgali Tepe).

Photo 3 Shallow dipping silicified fine grained sediments deposited in a sub aqueous setting overlying intensely argillic altered porphyry intrusive. These sediments likely deposited in small lakes formed within extensional basins within the north-east trending inferred graben structure at Hacidevisler (approximately 477750 E 4422800 N). The silicified sediments lack some key indicators to be called sinter, e.g. anomalous Hg, oriented plant clasts, silica falls developed on the sinter edge but do contain sedimentary bedding and fragments of silicified wood.

Photo 4 Chalcedonic to opaline silica veining exposed along the north-western margin of a north-east trending inferred graben structure at Hacidevisler (approximately 477750 E 4422800 N). This silica veining is interpreted to be developed on northeast trending extensional structures and developed at a near surface (within or immediately below the paleowater table) epithermal setting.

Photo 5 Breccia textures from within the 060-080 trending inferred structural corridor SW Pirentepe (approx 480100E 4420900N). Clasts are silicified porphyry with hematitic rims, sometimes as specularite, and a later dusty hematite coating. Voids within the hematite can be infilled with fine banded chalcedony indicating a late silica event.

Photo 6 Weak to moderate propylitically altered feldspar-quartz-hornblende altered porphyritic intermediate intrusive exposed to the north of Pirentepe at approximately 480700 E 4423000 N.

Photo 7 Selected drill core section from PD-01 (52.80 m to 56.80 m) comprising pyritised andesitic tuffs. The interval from 55.70 m to 56.80 m assayed 1.10 m at 3.15 g/t gold and 40 g/t silver.

Halilağa Photographs

Photo 8 View to the NW showing Pirentepe in the middle distance and Kirazli on the skyline. In the foreground is the distinctive vegetation anomaly to the north of the quartz porphyry of the Central Zone.

Photo 9 Sheeted and cross cutting quartz veins within quartz porphyry of the Central Zone

Photo 10 Goethite-hematite matrix breccias cross cutting sheeted and stockwork veined quartz porphyry in the Central Zone. The breccia clasts consist of wall rock and are monolithic. The late breccias are interpreted to be related to late extensional faulting.

Photo 11 Quartz-alunite altered dacite with late stage hematite-limonite veining from SE of Kunk Tepe.

Photo 12 Monolithic clast supported matrix breccia with silicified fine grained tuff clasts in an iron rich matrix composed largely of hematite and limonite. Similar breccias were anomalous in gold at Pirentepe.

Photo 13 Well developed crackle breccia with 0.5 cm wide hematite matrix fill including small clasts of broken wall rock. Previous samples from this area produced anomalous gold and is interpreted to be within a zone of early silicification as a result of an upflow zone, which later was brittlely deformed allowing circulation of oxidising surface waters.

Photo 14 View of the Central Zone vegetation anomaly developed as a result of near surface leaching and geochemical anomalism. Hole HD-01 is collared on the surface oxidised quartz porphyry in the centre right of the photo.

Photo 15 Detail of drilling rig and landscape of the Central Zone.

Photo 16 Representative drill core from HD-01 at 120.m depth, sericite-magnetite altered intermediate felsic (feldspar-quartz) porphyry with 7% magnetite, 8% quartz stockwork, 2% pyrite, 0.5% chalcopyrite. 119.90 m to 121.0 m assayed 0.248 ppm Au and 2440 ppm Cu.

Item 3 Summary

The author was engaged by Fronteer Development Group Inc. (Fronteer) in February, 2007, to complete a NI43-101 compliant report on the Halılağa (including Halılaga North) and Pirentepe properties, which form part of a larger permit holding within the Biga group of permits in the Çanakkale province of Western Anatolia, Turkey.

The author is not aware of any prior ownership or exploration activity within the Central Zone area of the Halılağa property and the porphyry hosted copper-gold mineralisation located in this area is a new discovery. The Pirentepe prospect and Halılaga North prospects have been held by Maden Tetkik ve Arama Genel Müdürlü (General Directorate of Mineral Research and Exploration, MTA) which is a department of the Turkish Government.

The Halılağa, Halılağa North, and Pirentepe prospects are located in the south central part of the Biga Peninsula in Western Turkey. Basement rocks of the Biga Peninsula consist of Paleozoic metamorphic rocks and Mesozoic mélanges of eglocites, clastic and carbonate lithologies. Examples of these lithologies occur within, or immediately outside the mapped areas. Granitic and granodiorite intrusives cut the basement rocks and are overlain by cal-alkaline and alkaline volcanics ranging in age from 35-23 Ma. A Miocene andesitic volcanic suite includes andesite, latite, dacite, rhyodacite lava dome facies, and volcanoclastic sequences including ignimbrites and is related to partial melting of the crust during N-S compression and crustal thickening, and later extension. At Halılağa, Halılağa North, and Pirentepe, the andesites are interpreted to be volcanic to sub-volcanic, with an overlying and intercalated sheet, or sheets, of varying tuff units, now present only as silicified cap remnants at higher elevations.

The Pirentepe and Halılağa prospects are interpreted to be a single widespread mineralised system containing porphyry related high-sulphidation style gold, and copper-gold mineralisation. Halılağa North is interpreted to be a structurally controlled high-sulphidation system distal to a high level intrusive. The mineralised intrusives are interpreted to be related to the 35-23 Ma granites and granodiorites.

Drilling by Fronteer at **Pirentepe** returned the following results:

- PD-01 intersected 1.79 grams per tonne gold over 46.90 metres, starting at 17 metres depth. The hole ended in high-grade gold mineralization.
- PD-02 intersected 1.83 grams per tonne gold over 38.0 metres also starting at 17 metres.

Further drilling is required to define the limits and orientation of the mineralisation which is hosted in pyritised andesitic tuff sediments. Lacustrine sediments are mapped up to 2 km from the known mineralised zone indicating potential for discovery of more pyritised sediments in fault depressions. Mineralised intersections given above may not indicate the true width.

Porphyry copper-gold mineralisation at the **Central Zone** within the **Halilağa** property has been identified in the newly discovered Central Zone. Mineralization occurs over the full length (298.2 m) of the first drill hole in this area (HD-01). Drill hole HD-01 intersected:

- 0.50 grams per tonne gold and 0.53% copper over the entire length of 298.2 metres, including 1.03 grams per tonne gold and 1.03% copper over 105.4 metres. Both intervals start from surface.
- A thick zone of secondary copper enrichment returned 2.15% copper and 0.93 grams per tonne gold over 25.8 metres starting at a depth of 23.8 metres.

HD-01 was collared in the central part of Central Zone in oxidized feldspar-quartz porphyry with a stockwork of 25-30% quartz veins to 23.95m. The supergene acid leach alteration zone, with 10% veining, 2% pyrite veins and chalcocite on fractures was intersected from 23.95-55.0m. Below the supergene alteration, the vein stockwork increases to 35-50% with 5-15% magnetite, 2-5% pyrite, >2% chalcopyrite and minor chalcocite and molybdenite. This veining mostly obliterated the original intrusive texture. A fault was intersected from 98.2-99.3m. Below the fault, the feldspar-quartz porphyry was potassic altered with sericite-magnetite-biotite-quartz, with zones of silica flooding and quartz veins varying from 8-40%, 2-5% pyrite and 0.5-1% chalcopyrite to about 154.2m. Below this the core has mostly biotite>magnetite alteration and usually >5% quartz veining; with zones of pink potassic alteration and few silica flooded zones. Pyrite veins and minor chalcopyrite was seen throughout the hole. From 286-298.2m, the hole ended in a siliceous green diorite.

At Halilağa 39.5 line kilometres of IP Chargeability/Resistivity and 43.5 line kilometres of ground magnetic surveying was conducted. The most significant anomaly generated is the coincident chargeability magnetic anomaly associated with the Central Zone porphyry copper-gold mineralisation intersected by hole HD-01.

The IP chargeability profile across the Central Zone (Line 8) shows a chargeability anomaly associated with the mineralised quartz porphyry centred on station 1400N with a depth profile in excess of 200 m.

Ground magnetics defines the magnetite alteration zone over an area of about 600m by 400 m. If smaller satellite magnetic anomalies to the east are included, it appears that the target area has a footprint of 1200 m by 400 m with a depth extent of approximately 200 m based on chargeability. The Central Zone has potential for copper-gold mineralisation to extend to the limits of the geophysical anomalies.

At **Halilağa North** Rock chip sampling has defined a strongly gold anomalous trend over 1000 m by 200 m oriented in a ENE direction, immediately north of the village of Halilağa. The highest grade rock chip sample was 1.24 g/t Au. Soil sample anomalies confirmed this trend and returned a peak gold result of 91 ppb Au. A strong chargeability anomaly is indicated to a depth of 150 m and a width of approximately 400m on line 489000E (line 90, Figure 8). At surface, the chargeability anomaly is associated with a strong resistor which extends to 100m depth over a width of 100 m. These anomalies are strongest on the western most IP line (line 90) suggesting that sulphidic mineralisation may occur at depth to the west and under cover.

Continued exploration is warranted on the Pirentepe, Halilağa and Halilağa North prospects properties. In-fill and extended geophysical surveys (IP Gradient Array, Dipole-dipole IP as well as detailed ground magnetics) should be conducted over the known targets (Davulgalı Tepe PD-01 and PD-02 Pirentepe), Central Zone (HD-01 Halilağa), and Halilaga North, prior to, or in conjunction with continued drilling

Successful definition of targets by geophysical surveys and the current drill programme will result in a decision point to undertake further drilling.

A proposed budget for the next two stages of exploration (infill geophysics and drilling) at Pirentepe (1800 m RC drilling), Halilağa (central Zone - 2400m RC and 3000m core), and at Halilağa North is recommended. Estimated budgets are: Pirentepe \$859,316, Halilaga (Central Zone) \$1,626,782 and Halilaga North \$572,877.

Item 4 Introduction and Terms of Reference

The author was engaged by Fronteer Development Group Inc. (Fronteer) in February, 2007, to complete a NI43-101 compliant report on the Halilağa (including Halilaga North) and Pirentepe properties, which form part of a larger permit holding within the Biga group of permits in the Çanakkale province of Western Anatolia, Turkey.

The report has been prepared so that new information on the Halilağa, Halilaga North, and Pirentepe prospects can be reported to a NI43-101 compliant standard.

Sources of information and data contained in this report, other than the author's direct observations, are cited in the text and referenced at the end of the report.

The author was extensively involved in geological field work conducted by Fronteer within the Halilağa and Pirentepe properties. This field work was undertaken within the period from July to September 2005 (Pirentepe) and July-August 2006 (Halilağa, and Halilaga North). Selected drill core from the Pirentepe and Halilaga prospects was reviewed during early December 2006. The author also had a role in reporting and making recommendations for soil sampling programmes, IP surveys and drilling programmes during and after these times, but was not directly involved in the activities. These surveys were undertaken by either Fronteer personnel, TeckCominco Arama ve Madencilik San. A.S. (TCAM) personnel or contractors to Fronteer. The Fronteer personnel directly supervising the field work were Brenda Hodgins and Lindsay Hall. Lindsay Hall is a Qualified person as per the requirements of NI43-101.

Item 5 Disclaimer

In preparing this report, the author has relied on data and information relating to quality assurance and control that has been prepared by a person who is not a Qualified Person as defined by the requirements of NI43-101. The name of this person is Brenda Hodgins. The author disclaims all responsibility for the parts of this report which refer to quality assurance and control.

In addition, the author has relied on data and information relating to geophysical surveys conducted at Pirentepe and Halilağa that has been prepared by persons who are not Qualified Person as defined by the requirements of NI43-101. This data is contained in the report by JS Jeofizik Servisi ve İleri Teknolojiler Ltd.Şti. (2006) Çanakkale/Çan Halilağa and Pirentepe Geophysical Survey for Gold Mining area. Survey report 2006. The author disclaims all responsibility for the parts of this report which refer to geophysics.

Item 6 Property Description and Location

Fronteer has numerous properties held in joint venture partnership with Teck Cominco Arama ve Madencilik Sanayi Ticaret A.S. (TCAM) in the Biga Peninsula area of north-western Turkey. This report is limited to the Pirentepe and Halilağa properties which form part of the Biga Properties centred at approximately 477500E 4424000N and 484000E 4418000N respectively (UTM Central meridian 27 (ED50 datum). See also Table 1 and Figure 1. The Pirentepe and Halilaga prospects are located about 25 km WSW of Çan, the nearest major town (Figure 2), while the Hlailağa North prospect is located about 20 km WSW of Çan and about 7 km south of Etili.

During 2004, the Company signed a letter of intent with Teck Cominco Limited's Turkish subsidiary, TCAM to acquire a 100% interest in five gold properties located in Western Turkey. Fronteer completed its technical due diligence and on April 27, 2004, May 6, 2004 and October 19, 2004, signed Letters of Agreement on three properties, the Agi Dagı Property, the Kirazlı Property and the Biga Properties respectively.

Under the terms of the option agreements, the Company was required to issue to TCAM a total of US\$500,000 worth of its shares upon signing, allocated as to 300,000 common shares to the Agi Dagı property, 200,000 to the Kirazlı property and 111,930 to the Biga Properties. Subsequent to December 31, 2004, the Company issued the shares required for the Biga Properties, completing its initial commitment to issue shares, for all five properties.

To earn a 100% interest in the Biga Properties, Fronteer was required to incur US\$2,000,000 on exploration over four years, with a first year firm commitment of US\$200,000. Upon earning 100% interest, TCAM will retain a Net Smelter Return Royalty of 1% on the properties.

TCAM notified Fronteer of their decision to back in on Pirentepe and Halilağa (and TV Tower/Dededagi) on November 30, 2006. They now have 3 years to spend 3.5 times the Fronteer Biga expenditures to date (50% of this must be spent in the first year).

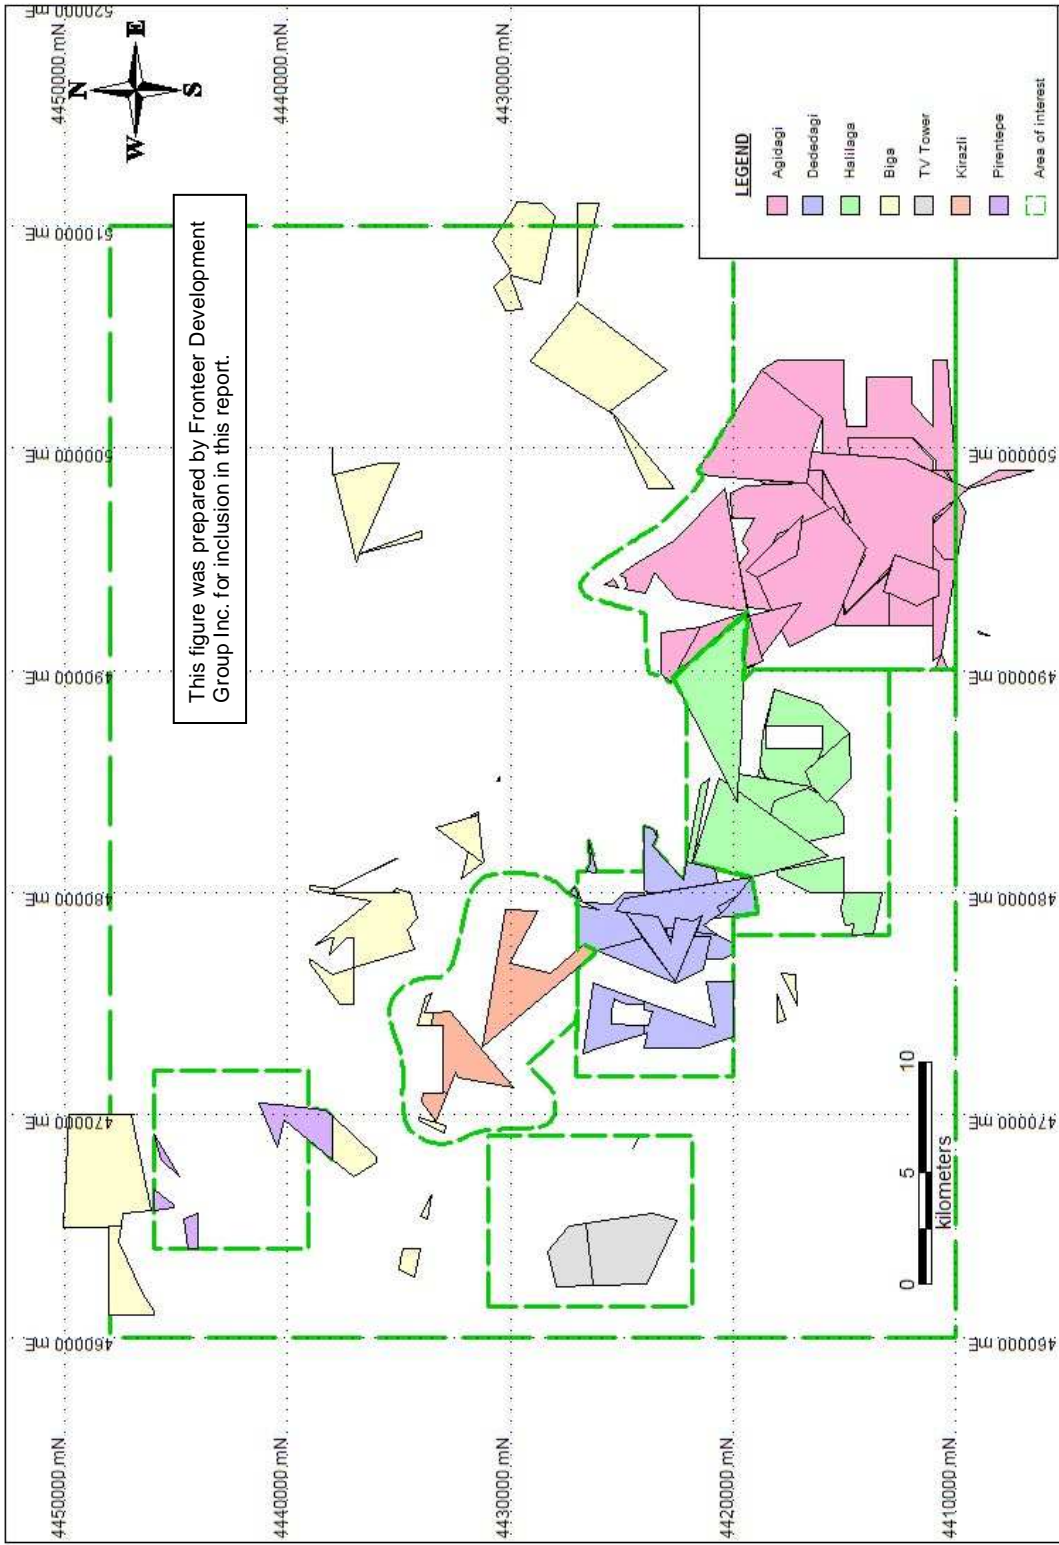

Figure 1 Location of Haliğa (including Haliğa North) and Pirentepe permit blocks and adjacent projects, Kırızlı and Ağı Dağı.

The author is not aware that the properties have been surveyed, or that there is a requirement to do so. Mineralised zones are shown on figures and maps accompanying this report. There are no known mineral resources, mineral reserves, mine workings, existing tailing ponds, waste deposits or important natural features and improvements.

The author is not aware that the properties are subject to environmental liabilities other than those attached to drill site permits issued to Fronteer.

No other permits must be acquired to conduct the work proposed for the property.

Item 7 Accessibility, Climate, Local Resources, Infrastructure and Physiography

The Biga Peninsula (Figure 2) has fertile soils and a Mediterranean climate with mild, wet winters and hot, dry summers. Temperatures range from 15 to 35 degrees Celsius in the summer season and -20 to -10 degrees Celsius in the winter months. The annual rainfall is approximately 30 cm, generally falling as mixed rain and snow in late fall and winter. Year-round access to the properties for field exploration is unrestricted due to weather however; snow falls during winter may restrict vehicle movement.

The region is well-serviced with electricity, transmission lines and generating facilities, the most significant being a large coal-fired power plant outside the Town of Çan. Population and agricultural activity is concentrated in the valleys, while most areas of active exploration are located in highlands which are predominantly forested and owned by the state.

Local labour is employed from nearby villages. There is no exploration infrastructure located within the properties.

No assessment of the sufficiency of surface rights for mining operations, the availability and sources of power, water, mining personnel, potential tailings storage areas, potential waste disposal areas, heap leach pad areas and potential processing plant sites has been undertaken as part of this report.

Item 8 History

The author, and Fronteer, is not aware of any prior ownership or exploration activity within the Central Zone area of the Halılağa property. The Pirentepe prospect and Halilaga North prospects have been held by Maden Tetkik ve Arama Genel Müdürlü (General Directorate of Mineral Research and Exploration, MTA, 1975) which is a department of the Turkish Government. The results of exploration conducted within these prospects by MTA are summarised in the sections on exploration.

The author is not aware of any previous mineral resource or reserve estimates or mineral production from either property.

Figure 2 Location of the Halilağa, Halilaga North, and Pirentepe properties, Western Anatolia, Turkey (base map from <http://www.washingtoninstitute.org/mapImages/41f5364065e32.jpg>)

Item 9 Geological Setting

The Halilağa, Halilağa North, and Pirentepe prospects are located in the south central part of the Biga Peninsula in Western Turkey. Basement rocks of the Biga Peninsula consist of Paleozoic metamorphic rocks and Mesozoic mélanges of eglocites, clastic and carbonate lithologies (Figure 3). Examples of these lithologies occur within, or immediately outside the mapped area. Granitic and granodiorite intrusives cut the basement rocks and are overlain by cal-alkaline and alkaline volcanics ranging in age from 35-23 Ma. A Miocene andesitic volcanic suite includes andesite, latite, dacite, rhyodacite lava dome facies, and volcanoclastic sequences including ignimbrites and is related to partial melting of the crust during N-S compression and crustal thickening, and later extension. At Halilağa and Pirentepe, the andesites are interpreted to be volcanic to sub-volcanic, with an overlying and intercalated sheet, or sheets, of varying tuff units, now present only as silicified cap remnants at higher elevations.

During extension, calc-alkaline intermediate lavas and pyroclastic rocks were extruded along NNE trending fractures and faults. The Lower-Middle Miocene successions were deformed under a compressional regime at the end of the Middle Miocene. The deposition of the overlying Upper Miocene-Lower Pliocene volcanic successions was restricted to within ENE trending graben basins. The graben bounding faults are oblique to the N-S compression/extension and incorporate a major strike-slip displacement formed during extension.

Late NE trending structures are related to development of graben structures during recent extension.

In the regional context, Halilağa, Halilağa North and Pirentepe include a number of the lithological and structural components of the Biga peninsula.

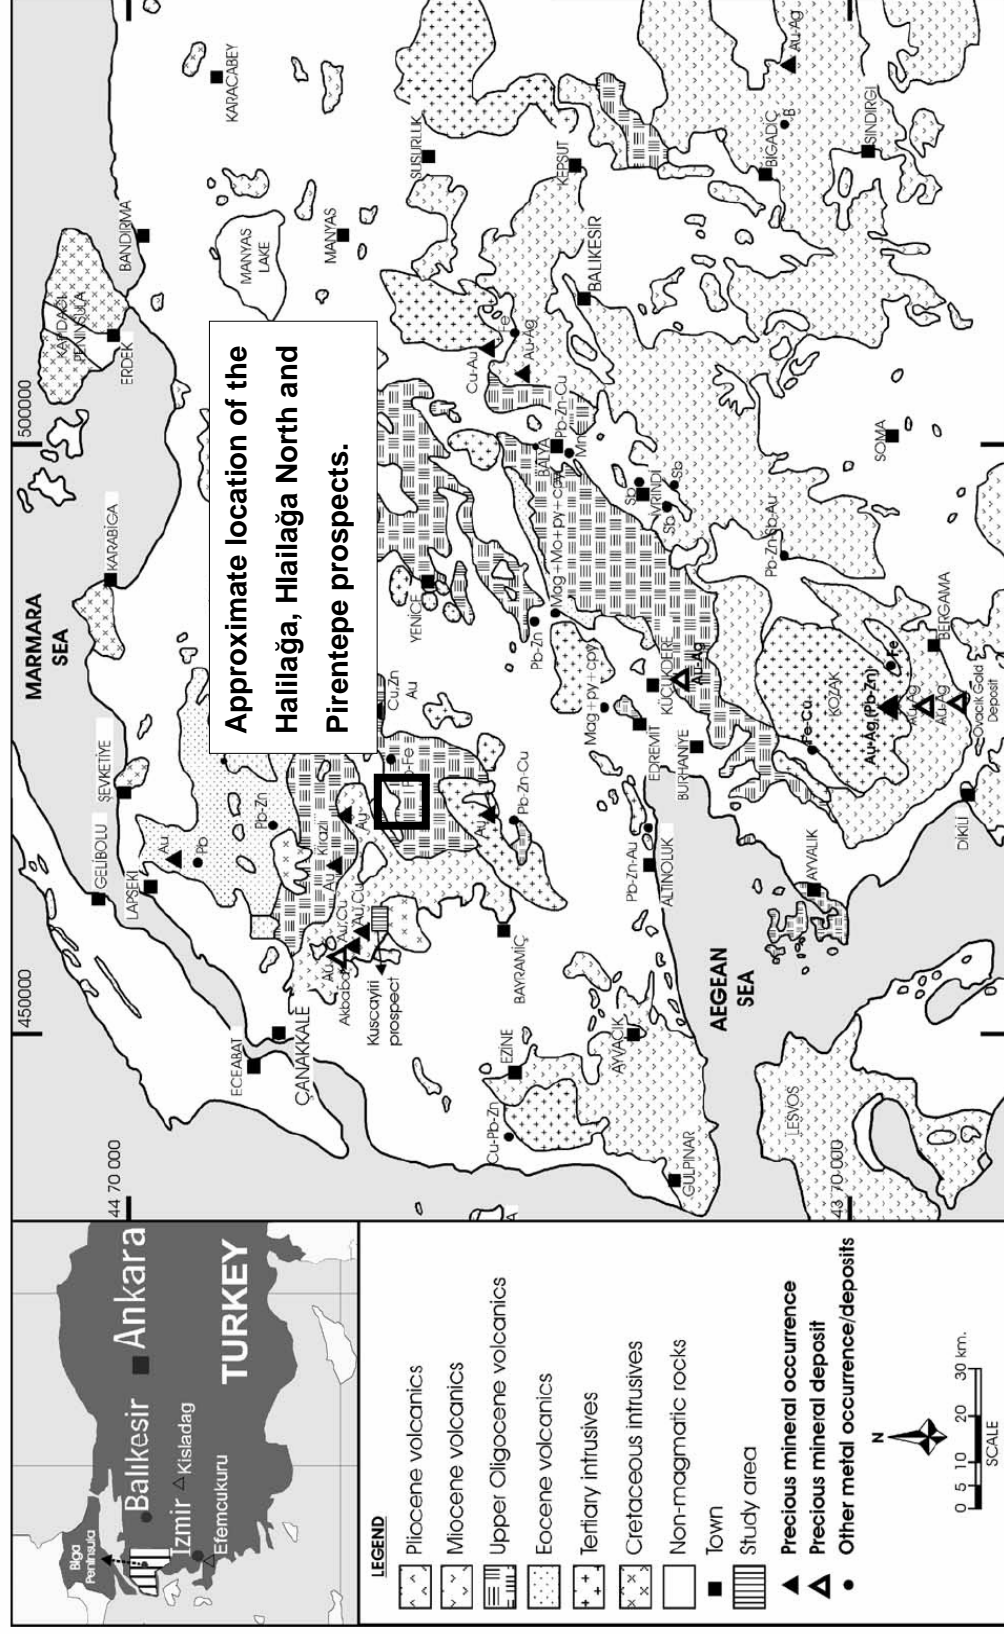

Figure 3 Geology of the Biga Peninsula and approximate location of the Halilağa, Halilağa North, and Pirentepe properties (figure from Yilmaz, 2003)

Item 10 Deposit Types

The Pirentepe and Halilağa prospects are interpreted to be a single widespread mineralised system containing porphyry related high-sulphidation style gold, and copper-gold mineralisation. Halilağa North is interpreted to be a structurally controlled high-sulphidation system distal to a high level intrusive.

Item 11 Mineralization

To date gold and copper-gold mineralisation has been defined by drilling undertaken by Fronteer in two localities, Davugali Tepe in the west of the Pirentepe property, and at the Central Zone in the Halilağa property. Drilling at Pirentepe (PD-01 and PD-02) has defined strong gold mineralisation in strongly pyritic tuffaceous sediments interpreted to be altered and mineralised as a result of the interaction of high-saline mineralised fluids discharging into carbonaceous rich sediments distal to the magmatic source of the fluids.

This model is supported by common fossil plant fragments seen in outcrops in correlated units and high mercury values. The silica cap lithologies which form higher elevated ridges and terraces in the Pirentepe area are weak to un-mineralised with respect to gold and probably acted as aquatards to mineralising fluids.

Drilling by Fronteer in this area returned the following results:

- PD-01 intersected 1.79 grams per tonne gold over 46.90 metres, starting at 17 metres depth. The hole ended in high-grade gold mineralization.
- PD-02 intersected 1.83 grams per tonne gold over 38.0 metres also starting at 17 metres.

Further drilling is required to define the limits and orientation of the mineralisation which is hosted in pyritised andesitic tuff sediments. Lacustrine sediments are mapped up to 2 km from the known mineralised zone indicating potential for discovery of more pyritised sediments in fault depressions.

Porphyry copper-gold mineralisation at Halilağa has been identified in the newly discovered Central Zone. Mineralization occurs over the full length (298.2 m) of the first drill hole in this area (HD-01). Drill hole HD-01 intersected:

- 0.50 grams per tonne gold and 0.53% copper over the entire length of 298.2 metres, including 1.03 grams per tonne gold and 1.03% copper over 105.4 metres. Both intervals start from surface.

- A thick zone of secondary copper enrichment returned 2.15% copper and 0.93 grams per tonne gold over 25.8 metres starting at a depth of 23.8 metres.

HD-01 was collared in the central part of Central Zone in oxidized feldspar-quartz porphyry with a stockwork of 25-30% quartz veins to 23.95m. The supergene acid leach alteration zone, with 10% veining, 2% pyrite veins and chalcocite on fractures was intersected from 23.95-55.0m. Below the supergene alteration, the vein stockwork increases to 35-50% with 5-15% magnetite, 2-5% pyrite, >2% chalcopyrite and minor chalcocite and molybdenite. This veining mostly obliterated the original intrusive texture. A fault was intersected from 98.2-99.3m. Below the fault, the feldspar-quartz porphyry was potassic altered with sericite-magnetite-biotite-quartz, with zones of silica flooding and quartz veins varying from 8-40%, 2-5% pyrite and 0.5-1% chalcopyrite to about 154.2m. Below this the core has mostly biotite>magnetite alteration and usually >5% quartz veining; with zones of pink potassic alteration and few silica flooded zones. Pyrite veins and minor chalcopyrite was seen throughout the hole. From 286-298.2m, the hole ended in a siliceous green diorite.

The Central Zone is exposed over an area measuring 300 metres by 400 metres; however, its geophysical footprint, defined by IP chargeability and magnetic anomalies is much larger, covering an area measuring 1,200 metres by 400 metres.

Results from HD-01 include:

| | From | To | Length | Au (g/t) | Cu (%) |
|------------------------|-------|--------|--------|----------|--------|
| Entire Interval | 0.00 | 298.20 | 298.20 | 0.50 | 0.53 |
| Leached Zone | 0.00 | 23.85 | 23.85 | 0.83 | 0.06 |
| Supergene Zone | 23.85 | 49.60 | 25.75 | 0.93 | 2.15 |
| Hypogene Zone | 49.60 | 298.20 | 248.60 | 0.42 | 0.41 |
| Interval 0.5 cutoff Au | 0.00 | 105.40 | 105.40 | 1.03 | 1.03 |

High temperature contact style mineralisation occurs at Kumluggedik Tepe where quartzites and carbonates have been propylitically altered. High temperature mesothermal quartz veining occurs within gold mineralised float of intermediate volcanics (with some quartz eyes). The exposure is limited in this area and trenching is required to better identify the style of mineralisation.

Item 12 Exploration

The exploration undertaken by Fronteer on the Halılağa, Halilaga North, and Pirentepe properties during 2005 and 2006 is described below.

Statistics on sample numbers, type and coverage of geophysical surveys is shown in Table 2 (data supplied by Fronteer).

| | | Rock | Soil | Silt | Drill | IP (line km) | Magnetics (line km) |
|----------------|--------------|------------|-------------|----------|-------------|--------------|---------------------|
| Pirentepe | 2005 | 345 | 1135 | 0 | 0 | 36.9 | 0 |
| | 2006 | 0 | 119 | 0 | 1074 | 5.2 | 14.85 |
| | TOTAL | 345 | 1254 | 0 | 1074 | 42.1 | 14.85 |
| Halılağa | 2005 | 142 | 232 | 0 | 0 | 7.5 | 0 |
| | 2006 | 52 | 349 | 0 | 359 | 32 | 43.5 |
| | TOTAL | 194 | 581 | 0 | 359 | 39.5 | 43.5 |
| Halılağa North | 2005-6 | 35 | 152 | 0 | 0 | 3.2 | 0 |
| | TOTAL | 35 | 152 | 0 | 0 | 3.2 | 0 |

Table 2 Exploration samples and geophysical surveys, Halılağa, Halilaga North, and Pirentepe properties, 2005-2006.

Item 12.1 Pirentepe

Previous exploration

- The Pirentepe area was mapped and sampled by an MTA-Metal Mining Agency of Japan JV in 1975 (MTA, 1975) which concluded that:
- The area was comprised of andesitic lithologies ranging from lavas to tuffs. The andesites were noted as being generally coarsely crystallized and in some areas appeared granitic.
- Alteration ranged from unaltered to argillic with silicic alteration being restricted to isolated higher peaks, particularly Küçükdağ Tepe, Büyükçukur Tepe, Celdiren Tepe and Pirentepe.
- Silicified zones consist of massive, brecciated and porous parts. MTA observed that the massive silicified zones occur in the central parts of the silicified zones and pass outward to porous and brecciated areas and that they contain hematite and limonite.
- MTA noted that the silicified zones were identified on air photographs (presumably these were used to map the distribution of the silicified zones, therefore they should be reasonably well located). No comment was made on the structural setting of the area due to the extensive distribution of the

volcanics, however joints and fissures were noted as trending NE-SW. A trench survey (334 m in total length) was conducted at Davulgalı Tepe within a limonitic argillic altered zone with samples being collected from the B-C soil horizon. Best gold results were obtained from the silicified zone in the westernmost trench (up to 280 ppb gold) while limonite-argillic zone peaked at 80 ppb, however most samples were below the detection limit of 5 ppb gold. A two hole drill programme totalling 302 m was completed at Davulgalı Tepe to test the alteration zones exposed in the trenches. The easternmost hole (MJTC-2) encountered >100 ppb gold in a limonitic argillic-silica altered zone from 18.00 m to 54.20 m. This zone averaged 700 ppb gold over 36.20 m. In addition silver, mercury and antimony are elevated over this zone (9.3 ppm Ag, 2400 ppb Hg, and 180 ppm Sb). Peak gold value in this hole is 3 m at 4400 ppb from 48 to 51 m. Hole MJTC-1 did not encounter gold above 25 ppb. Rock chip sampling was conducted over the Pirentepe area by MTA with 134 samples assayed for Cu, Pb, Zn, Au, Ag, Mo, Hg, As, F, Ba, Ti, and Se. Note that most anomalous gold samples (>100 ppb gold) lies within a zone trending 060 from the southern margin of the silica cap in the east to Davulgalı Tepe in the west (and is coincident with a Bi-As-Cu-Fe anomalous soil zone defined by Teck soil sampling – see later). The peak gold value from MTA sampling was 2060 ppb Au. This locality was revisited and it would appear that this sample was taken from silicified float rock cleared from adjacent fields.

- TeckCominco undertook reconnaissance soil sampling and rock chip sampling in 2000

Fronteer 2005 -2006

In July and August 2005 the following activities were undertaken by the author and were reported on in Grieve (2005). Drilling in 2006 is discussed separately.

- interpretation of linears from topographic base maps,
- reviews of previous mapping, drilling and rock chip and soil sample geochemistry,
- reconnaissance mapping was undertaken over the Pirentepe and Ada Tepe area (4 km to the west) to confirm that variations in alteration mineralogy, quartz

textures and lithologies were mappable and could be used to better define targets for follow-up exploration,

- detailed pit mapping and sampling,
- interpretation of previous wide spaced soil geochemistry, and
- partial field traverses within an area of extrapolated coincident Bi-As-Cu-Fe soil anomalism
- Mapping and sampling of exposures in drainages and track cuts within the southern part of the Pirentepe area identified above,
- Further reconnaissance scale mapping of the Ada Tepe and Pirentepe areas,

Mapping (Map 1, Photos 1 to 7))

Below are descriptions of the mapped geological units.

Geological units

Recent cover (Elluvial, Colluvial, and Alluvial)

On the southern slopes of Pirentepe cover units exist over significant areas and are likely to be deeper than 5-10 m so have been plotted as separate units. Bedrock geology here is likely to be weak to unaltered intermediate volcanics (andesite) to the south, and intermediate intrusives of the Pirentepe hill to the north. Scattered small outcrops of these lithologies exist within the incised gullies.

Conglomerates and sandstones

Bedded coarse volcanoclastic sediments outcrop south of the Çan-Bayramiç road at around 479500E 4419000N. These sediments are unaltered and are inferred to be younger than the alteration and mineralization at Pirentepe.

Silica Cap

Remnant silica cap rocks are present over extensive areas at Pirentepe, particularly on higher ground at Küçükdağ Tepe, Büyükçukur Tepe, Celdiren Tepe and Davulgali Tepe, and at Ada Tepe in the west. Within all these areas the protolith for the silica cap is interpreted to be extrusive volcanics of dacitic composition (based on presence of common qtz eyes and crystals in tuffs). Specific lithologies include tuffs (including crystal, and crystal-lithic tuffs, silicified wood to 20-30 cm in size is locally very

common) and flow breccias. The high primary permeability of these units would have allowed a greater flow of fluids. In the northeast, away from the central part of Pirentepe, the tuffs are less silicified, being distal to the inferred silica feeder.

Outcrops are generally small in extent and less than 10 m in thickness. The silica cap dips gently to the north. Where exposed (e.g. Pits 1 and 8), the contact between silica cap and argillic/advanced argillic altered porphyry is very sharp and flat lying indicating ponding of acid fluids beneath the silicified zone. Mapping of alteration and silica species within the silica cap shows common granular and saccharoidal vuggy silica indicating acid leaching and silica replacement. Geochemical sampling within massive to vuggy silica exposed within silica pits were generally barren with respect to gold (peak value of 0.033 ppm gold in Pit 9, Küçükdağ Tepe). Late hematite-limonite matrix breccias are barren within the silica cap. Silicified dacitic volcanic breccias in Pit 4 (Ada Tepe) contained anomalous copper to 152 ppm, Pits 3, 8 and 1 at Pirentepe contain anomalous arsenic values greater than 500 ppm (peak of 1220 ppm). The more anomalous geochemistry within these volcanic breccias is the result of a greater primary permeability within the breccias.

At Celdiren Tepe a late chalcedonic overprint (veining to 10 cm and void infill) within massive to saccharoidal vuggy silica (481519E 4421800N) has occurred likely as a result of decompressive boiling of a high silica concentration fluid within a brittly deformed silica cap. Sample results are awaited from the chalcedonic silica, however previous sampling in the close vicinity returned anomalous gold at 0.11 ppm.

Volcanic Tuff (V-ye)

This tuff unit outcrops in the NE of Pirentepe and is commonly argillic altered with leiseegang rings developed in finer units. The tuff is likely to be a distal equivalent of the volcanic flow breccias and tuffs nearer the central part of Pirentepe. The tuff is cut by later silica-pyrite altered porphyry dykes striking 108 (field locality 530).

Kirtaş Tepe Andesite

This propylitically altered coarse andesite occurs at 479000E 4419000N in the southern part of the mapped area. The unit is coarser than other units mapped as volcanic (andesite) and is propylitically altered.

Lacustrine bedded sediments (V-Lac)

NNE and SSW of Hacidevrisler chalcedonic silica replaced finely bedded sediments (with leafy plant fossils) occupy the western part of an inferred NE trending graben

structure. The sediments are likely to be the distal equivalents of the tuffs at Pirentepe. The abundance of chalcedonic float and late chalcedonic silica veins along this structure indicates potential for a low sulphidation epithermal setting coeval with the high sulphidation setting at Pirentepe.

Subvolcanic intrusives/extrusives (II-V-po)

This unit is interpreted to be an early andesitic phase of volcanism through which the porphyry stocks of Küçükdağ Tepe, Büyükçukur Tepe, Celdiren Tepe and Davulgali Tepe intruded with subsequent development of the silica caps and alteration. This unit is weak argillic to unaltered to the north and south of Pirentepe and when unaltered and not oxidised can be strongly magnetic. East of Söğütgediği the andesite is variously altered from intense argillic to weak, or unaltered. If the Kirtas Tepe Andesite is included in this unit then that andesite would be an indication of a very distal propylitically altered zone. To differentiate this unit from the intermediate intrusives, the andesites contain smaller feldspar phenocrysts in a groundmass of fine feldspar laths. Outcrops show common ‘layering’ and show enough variations in phenocrysts size and groundmass composition to suggest a volcanic setting. These features are absent from the units mapped as intermediate intrusives which tend to be more massive and have coarser feldspar, hornblende, biotite and quartz phenocrysts.

Pirentepe Intermediate Intrusives (II Po)

Intermediate intrusives with varying phenocrysts mineralogy form the higher ground of Pirentepe and Ada Tepe. The intrusives generally contain coarse feldspar phenocrysts with subordinate hornblende, biotite, quartz, and rare muscovite. Three mineralogically distinct intrusives were recognized and are spatially distributed in significant clusters:

1. Feldspar-biotite +/- hornblende and quartz
2. Feldspar-hornblende +/- biotite and quartz
3. Feldspar-quartz +/- biotite and hornblende

The feldspar-quartz intrusive is spatially related to anomalous soils at Davulgali Tepe the distribution of chalcedonic silica and are likely to be the source of the silica rich fluids that formed the silica cap within the extrusive lithologies above the porphyry units.

Structure

Linear trends defined by ridges, valleys, and breaks in slope were interpreted for the two topographic map sheets covering the Pirentepe-Ada Tepe area. Three inferred structural sets are present:

1. The Pirentepe silica cap appears to be bounded by EW linears to the north and south, and to the east by a near NS linear. A NS linear cuts the silica cap at around 481000E. Detailed pit mapping showed evidence for faulting of the silica cap on both these orientations. Au, Pb, Cu and As are anomalous in rock chip sampling from near a N-S drainage along 480500E. These are inferred to be late structures. The spatial distribution of the larger silica caps at Küçükdağ Tepe, Büyükdağ Tepe and Celdiren Tepe suggests an E-W oriented control over their formation, though no field evidence was found to support this.

2. A zone trending approximately 060 to 080 extending from SW of Davulgalı Tepe to the eastern limit of the silica cap, west of the village of Muratlar. This structure is defined by linear drainages and ridges in the west and breaks in slope along the southern margin of the silica cap in the east, where it trends more easterly. Jointing subparallel to this trend was measured in one outcrop. This zone is also coincident with anomalous drill hole results in hole MJCT-2, rock chip and soil geochemistry, and mapped brecciated silica +/- hematite and limonite oxidation.

3. NE trending linears defined largely by the Hacıdevrisler valley that separates Pirentepe from Ada Tepe, and two less continuous linears traversing the silica cap to the east. The linears within the Hacıdevrisler valley. In terms of mineralization, the important structural controls appear to be (letters relate to locations on the conceptual prospect model attached):

A and C) Localisation of silica caps (+/- vuggy silica) along an apparent E-W trend indicating a possible feeder zone to the silica within this zone;

B) A zone of silicification, brecciation, oxidation and late chalcedony +/- pyrite overprint within a 060-080 trending corridor along the southern margin of the silica cap in the west and cutting likely down faulted units of silica cap in the east resulting in brecciation.

D) An extensional basin at Hacıdevrişler accumulating finer grained tuffs and carbonaceous sediments with silica rich fluids ascending up NE trending structures from a distal part of the Pirentepe intrusive centers resulting in silicification of the sediments and chalcedonic veining (possible low sulphidation setting).

Alteration

Clay Alteration

Interpreted alteration is shown in Map 2. Generally the northern areas have less pervasive alteration styles (e.g. Küçükdağ Fire Tower road), that is, alteration passes rapidly between unaltered-chalcedony-argillic over short distances. Beneath the silica caps, and well exposed in Pit 3 and 8, advanced argillic/argillic altered coarse porphyry intrusive is exposed. On the southern margin intense argillic alteration crops out in association with a late chalcedony-pyrite event.

Silicification

Variations in silica species can be mapped across the silica cap, generally opaline-chalcedonic in the NW at Küçükdağ Tepe to dominantly saccharoidal silica in the SE at Pirentepe where commonly quartz phenocrysts are preserved within a dacitic tuff, flow breccia and trachydacite protolith . The chalcedony-opaline silica can be interpreted as an indicator of the paleowater table level. The saccharoidal silica indicates silicification at a deeper level and conceptually this could occur within the root of a system. Vuggy silica is locally developed but has mostly been recrystallised to either opaline-chalcedony or saccharoidal quartz.

A separate silica event occurs within the 060-080 trending corridor of breccias in the southern part of Pirentepe where late chalcedonic infill, replacement and “veining” occurs in a breccia comprised of silicified and vuggy silica altered porphyry. The chalcedonic silica occupies voids within botryoidal limonite-hematite as matrix to breccias, as cross cutting replacement of porphyry breccias and as a chalcedony-py breccia zone trending 330 associated with strong argillic alteration. This chalcedonic zone is interpreted to be related to a lowering in the paleowater table as a result of down faulting of the southern margin of the target.

Note that silicification occurs with two protoliths at two quite different elevations. The upper silica cap is interpreted to be developed within a volcanic dacite unit consisting of tuffs, flow breccias, and trachydacite (as seen in the silica pits) accumulating at the paleosurface. These units would have had a high initial permeability and would preferentially be acid leached and later replaced by silica. On the southern margin of Pirentepe early vuggy silica and silicification occurs within the “basement” feldspar-biotite- hornblende porphyry. This is interpreted to represent a deeper zone of acid

leaching, possibly temporally related to silicification of the cap, but spatially at a lower level in the volcanic pile.

Geochemistry

Previous TCAM Soil Sampling

In 2000 Teck undertook a reconnaissance soil sampling programme over five N-S lines at Pirentepe and one short E-W line on Davulgali Tepe. A total of 107 samples were collected. Results from these samples were statistically analyzed to determine metal zonations.

Factor 1 Zn-Al-Mn-P-Mg-Ca-Sn-W

This association probably reflects oxidation within the soil horizon and scavenging of metals by Mn oxides.

Factor 2 Pb-Sb-As-Au-Mo-Bi, and Factor 6 Bi-Au

These two factors represent the mineralization event and the distribution of anomalous samples is coincident with anomalous drill hole results in hole MJCT-2, rock chip geochemistry and mapped brecciated silica +/- hematite and limonite oxidation.

Factor 3 Fe-Cu-P-As-K, Factor 4 Na-K-Mg-Ca-Cu, and Factor 5 Sn-Fe-Mo:

These factors have no clear spatial distribution.

2005 Fronteer Rock Sampling

Rock chip sampling was conducted over the prospect, however most sampling was undertaken in the Davulgali Tepe to Celdiren Tepe area along the trend of fracturing, brecciation and inferred extensional faulting. Sample locations and Individual plots for pathfinder elements Au, Ag, As, Mo, Cu, Pb, Zn, Sb, Hg, Bi, Mn, and P were reviewed in detail in Grieve (2005).

Multivariate statistical analyses were conducted on the dataset and while weak correlations between elements and metal associations between Mn-Zn-Ag, Bi-Cu-Sb, P-Mo-Hg, Pb-Mo-Sb, As-Ag, and Au-Hg-Ag (see below) were determined, no clear spatial relationship was indicated. This is probably a result of the limited coverage of the sampling.

Coincident anomalous trends with respect to Au, As, Cu, and P occur in the Davulgali Tepe to Celdiren Tepe trend highlighting this area as a potential significant zone of

mineralisation. The presence of elevated phosphorous indicates mobilisation of phosphorous from apatite in the intrusives and re-deposition in advanced argillic alteration zones. This process is a key indicator of advanced argillic alteration in high sulphidation systems.

2005 Soil Sampling

Soil sampling was undertaken on a approximate 200-300 m line spacing with samples collected every 50 meters between lines 476000 and 482200 E covering the areas from Ada Tepe in the west to Celdiren Tepe in the east. Individual plots for pathfinder elements Au, Ag, As, Mo, Cu, Pb, Zn, Sb, Hg, Bi, Mn, and P were reviewed in detail in Grieve (2005).

Correlation analysis of the dataset resulted in 6 factors being calculated (As-Sb-Pb, Mn-Zn-Au, Ag-Bi, P-Cu-Zn, Hg-Mo, and Mo-Au-P). The Mo-Au-P metal association which is closely associated with the Davulgali Tepe – Celdiren Tepe trend. This factor indicates porphyry related gold-molybdenum mineralisation associated with advanced argillic alteration and supports this trend as being the priority for continued exploration.

Item 12.2 Halilağa

The author is not aware that there has been any modern exploration conducted on this property. The activities conducted during 2005 and 2006 are discussed below. Drilling is described separately.

Mapping (Map 3, Photos 8 to 16)

Geology units

Colluvium

The prospect area (Map 3) is expensively covered by colluvium, particularly on the steeper slopes of the Kunk Tepe-Guvenmtasi Tepe-Tasyatak Tepe and Kumluggedik Tepe ridge line. In track cuts this colluvial cover can be up to 2 – 3 m thick reducing the total exposure of bedrock outcrop across the property to probably much less than 5 %.

The geology and alteration maps reported here (Maps 3 and 4) do not show this cover and are an interpretation of the underlying lithologies.

Polymict Conglomerate

Polymict conglomerates are widely distributed on the higher ground within the area mapped at Halilağa, particularly in the NW of the area. The conglomerate consists of rounded to sub rounded clasts of silicified tuff, porphyritic volcanics, and vein quartz in a chlorite/epidote altered matrix. The timing relationships are not clear; however the conglomerate is interpreted to be post volcanic/subvolcanic and pre quartz porphyry intrusion. Quartz clasts are possibly sourced from the granites to the south east of Halilağa.

Quartz porphyry

A quartz porphyry intrusive is well exposed in the Central Zone (named for the locality on the topography map). Previously soil sampling in the area has given results up to 1265 ppb gold. At surface quartz eyes are commonly preserved in a quartz rich matrix. Sheeted coarsely crystalline quartz veins occur in the eastern part of the porphyry where the rock is pervasively silicified and argillically altered \pm granular silica replacement of the matrix. Sheeted quartz veining is generally oriented E-W though this can vary through to N-S striking. The sheeted veins are cross cut by later hematite rich monolithic breccias with clasts comprised of quartz porphyry.

To the west the porphyry appears to be more phyllic altered (\pm argillic and silica) and the style of veining is restricted to E-W striking veins of coarse saccharoidal quartz up to about 30 cm in width.

There appears to be no previous rock sampling from this area. An extended soil sample grid was completed on 19-20 June to the north and west of the area.

The porphyry also appears to have hornfelsed clastic sediments to the west which are strongly pyritised. The contact zone between the porphyry and the hornfelsed sediment could be a significantly mineralised target due to increase development of veining and brecciation as a result of fluid flow constriction.

Volcanics/Subvolcanics

The dominant units within the mapped area are andesitic volcanics and sub volcanics and a feldspar-hornblende intermediate felsic subvolcanic with a significant quartz component enabling it to be differentiated from the andesites. Part of the andesite unit includes tuffs demonstrating that at least part of this unit is extrusives. Where the tuffs can be mapped over larger areas they have been identified on the geological map as a separate unit.

Inferred discontinuities between the tuff units and the andesite/tuff sequence, and the feldspar-hornblende-quartz volcanic as shown on the maps define the NW-SE trending structural linear along which the quartz-porphyry within the Central Zone and related acid fluids have localised resulting in alteration of these volcanic units.

Andesitic Tuffs

This unit forms part of the same volcanic pile as the andesites, however where enough outcrops were present, and there was sufficient confidence to map these as a differentiated unit they were depicted on the interpreted geology map as such.

Quartzites and carbonates

Basement clastic and carbonate sediments in the vicinity of historic mining activity at Kumluggedik Tepe have been variously altered to propylitic grade (chlorite, epidote, actinolite, quartz) as determined by thin section analysis (samples 533363 to 533367). This grade of alteration occurs at moderate to high temperatures in an alkaline setting and is transitional between mesothermal and epithermal. Some phyllic alteration is also present. Quartz vein float in this area has been previously been extensively sampled and is strongly anomalous in terms of gold and base metals fitting this model. Quartz textures are coarsely crystalline. Trenching of this area is required to expose the veining in outcrop to determine the mineralisation style.

Schistose basic volcanics and sediments

Scattered float on Bakirlik Tepe of schistose basic volcanics and sediments are likely to represent the Palaeozoic basement lithologies of the Biga Peninsula. No exposure of the units in situ was seen. These units are not mineralised.

Alteration

Alteration at Halilağa (Map 4) is zoned about an inferred NW-SW trending structure (identified by linears interpreted from topographic maps and QuickBird satellite imagery, and by the mapped lithologies). A quartz rich porphyry intruded sediments and volcanics in the Central Zone at the intersection of this structure and an ENE trending graben parallel fault zone, also identified by linear mapping. Acidic fluids derived from this porphyry have likely migrated along this NW-SW trending zone resulting in acid altered volcanics and massive silicification along the Kunk Tepe-Guvemtasi Tepe-Tasyatak Tepe ridge line (see conceptual model).

Approximately, 2 km to the NW from the Central Zone, along this same NW-SW trend, lies the priority target for drilling at Pirentepe defined by an increased thickness of silica cap (defined by resistivity), better soil and rock geochemistry and NW linears.

Sub propylitic

Sub propylitic alteration of the volcanics and sub volcanics is typically weak to moderate in intensity, pervasive and texture preservative. The occurrence of chlorite, smectite, and varying degrees of carbonate and pyrite define this alteration zone at Halilağa and grades out to unaltered lithologies in the NE and SW.

Argillic

A broad zone of argillic altered andesitic volcanics and tuffs is developed about the advanced argillic alteration zones forming the higher ground along the Kunk Tepe-Guvenmtasi Tepe-Tasyatak Tepe ridge line. Typically the alteration is texture preservative with feldspars altering to Kaolin and smectites and the groundmass being replaced by silica to varying degrees. The best exposures of this style of alteration are found in excavations for spring water on the NE flanks for Guvenmtasi Tepe.

Quartz-Alunite advanced argillic

Alteration along the NW trending ridge lines of Guvenmtasi Tepe and Tasyatak Tepe demonstrate distal alteration away from the inferred fluid source of the quartz porphyry at the Central Zone with a zonation from quartz-alunite altered andesites at Guvenmtasi to near complete silica replacement of tuffs and volcanics at Tasyatak Tepe. This zone is inferred to represent the distal outflow of acidic fluids from the porphyry source. Previous rock chip sampling along this zone demonstrates that this fluid phase resulted in deposition of anomalous (<1 ppm) gold. Soil sampling results gave localised anomalies with respect to gold, bismuth, and mercury and was not anomalous in terms of base metals.

Commonly the quartz-alunite alteration is cut by mm scale goethite-hematite veinlets generally trending NNE which are well exposed in saw cut channels. This later oxidising event may have elevated grades; however more detailed sampling would be required to determine this.

Silica Pyrite

Texture preservative and pervasive silica-pyrite alteration is mapped in the SW of the prospect within andesites and a felsic porphyritic volcanic (probably of dacite composition). A surficial argillic alteration zone has developed on weathered outcrops due to oxidation of pyrite. The silica pyrite alteration is inferred to be an early stage of alteration resulting from moderate temperature sulphur rich and metal poor fluids derived from a porphyry intrusion. Rock sampling to date has been limited in this area; however soil sampling shows that this area is not anomalous with respect to gold. Later higher temperature and more saline fluids resulted in gold deposition associated with the advanced argillic alteration developed along NW trending zones as described above. In this model, the advanced argillic alteration post dates and cuts the earlier silica pyrite alteration.

Silicification

Texture destructive silica replacement of tuffs and volcanics on Tasyatak Tepe resulted from distal siliceous fluids associated with advanced argillic alteration derived from a porphyry source. The zone here dips steeply to the NE and is approximately 25 m thick in outcrop.

Propylitic

Basement clastic and carbonate sediments in the vicinity of historic mining activity at Kumluggedik Tepe have been variously altered to propylitic grade (chlorite, epidote, actinolite, quartz) as determined by thin section analysis (samples 533363 to 533367). This grade of alteration occurs at moderate to high temperatures in an alkaline setting and is transitional between mesothermal and epithermal. Some phyllic alteration is also present. Quartz vein float in this area has been previously been extensively sampled and is strongly anomalous in terms of gold and base metals fitting this model. Quartz textures are coarsely crystalline. Trenching of this area is required to expose the veining in outcrop to determine the mineralisation style.

Argillic and phyllic alteration

The quartz porphyry located in the Central Zone is variously altered to argillic and phyllic facies end members indicating an overprinting of thermal and fluid conditions. Silicification and granular (saccharoidal) silica also represent varying temperature settings. Hornfelsed clastic sediments (basement?) to the west of the porphyry are assumed to be altered as a result of this intrusion.

Geochemistry

Silt sampling does not appear to have been undertaken within the Central Zone area at Halilağa.

A correlation analysis of previous soil sampling was conducted on the data set which highlighted a Au-Mo-Cu-Fe-Bi correlation factor. This correlation highlights the porphyry related mineralisation at the Central Zone and south west to Guvemtasi Tepe. The anomaly is strongest over the exposed sheeted and stockwork veined porphyry.

Rock chip sampling of oxidised and leached outcrops in the Central Zone area returned 19 samples out of 40 collected with gold values greater than 1.0 grams per tonne. Sample results include gold values of up to 2.3 grams per tonne, silver values of up to 90.8 grams per tonne, and copper values of up to 0.30%.

Item 12.3 Halilağa North

Previous Exploration

MTA (MTA 1975) conducted a regional scale exploration programme over the Biga Peninsula in 1975 and reported the results on areas of interest (MTA 1975). In the vicinity of the Halilağa village, MTA located zones of silicification and argillic alteration. North of Halilağa a zone of silicification extends over 700m by 150 m and trends NE-SW at Şağluk Tepe. Southeast of Halilağa at Taşkesilen-Kocataş Tepe silicification was mapped over 1000m by 300 m and trends NE-SW. MTA interpreted the silicification north of Halilağa as being structurally controlled. Silicified rocks contain iron oxides as limonite and hematite veins and disseminations. Disseminated pyrite occurs in un-oxidised silicified rock in drill core. Gold mineralisation occurs in the western part of Şağluk Tepe in silica-argillic altered zones. No description of the lithology at surface was made by MTA.

MTA drilled 2 core holes, MJTC-16 and MJTC-17 (each hole was 151 m in total depth) to test a geochemical anomaly identified by rock chip sampling (Map 5). Core samples were selectively analysed for gold, silver, copper, lead, zinc, antimony, mercury, and molybdenum, however no results for this sampling has been seen by the author. Petrology and XRD analysis was also undertaken, but have not been seen by the author.

Drill hole geology in hole MJTC-16 consisted of strongly silicified and argillised rock from 2.20 m to 16.65 m, and weakly argillised andesite from 16.65 m to 151.00 m. Drill hole geology for hole MJTC-17 was not included in the data provided to the author.

In 1997 TCAM collected 57 rock chip samples from silicified outcrops at Halilağa North. Highest reported gold result was 1.17 g/t gold.

Fronteer 2005-2006

In 2005-6 Fronteer appraised the alteration zone identified to the immediate north of the Halilağa village (Halilağa North) and conducted an exploration programme consisting of surface geochemical sampling (152 soil samples, and 35 rock chip and saw cut channel samples) and 3200 m of pole-dipole IP surveys (4 lines). The highest results from soil and rock sampling were 91 ppb and 1.24 g/t gold respectively. See Map 5 for locations of the soil and rock sample locations and IP line locations. This exploration was reviewed by the author and the area visited over 2 days in July 2006.

Rock chip sampling has defined a strongly gold anomalous trend over 1000 m by 200 m oreintd in a ENE direction, immediately north of the vllage of Halilağa. The highest grade rock chip sample was 1.24 g/t Au. Soil sample anomalies confirmed this trend and returned a peak gold result of 91 ppb Au.

Item 12.4 Geophysics

Item 12.4.1 Pirentepe and Halilağa

A total of 42.1 line kilometres of IP Chargeability/Resistivity and 14.85 line kilometres of ground magnetic surveying was conducted at Pirentepe. At Halilağa 39.5 line kilometres of IP Chargeability/Resistivity and 43.5 line kilometres of ground magnetic surveying was conducted. The most significant anomaly generated is the coincident chargeability magnetic anomaly associated with the Central Zone porphyry copper-gold mineralisation intersected by hole HD-01 (see Figures 4-7). JS Jeofizik Servisi ve İleri Teknolojiler Ltd.Şti. (2006) which documents the surveys undertaken was reviewed by the author.

The IP chargeability profile on Line 8 shows a chargeability anomaly associated with the Central Zone quartz porphyry anomaly centred on station 1400N with a depth profile in excess of 200 m. Also on this section at station 2200n a broad chargeability

anomaly at >200m from ground surface probably represents the initial widespread and barren silica-pyrite altered andesites and feldspar-hornblende-qtz subvolcanics.

Line 16 demonstrates a deep resistivity anomaly associated with the inferred outflow zone SW from the Central Zone quartz porphyry. The deeper chargeability anomaly is likely to be associated with the early and barren silica-pyrite alteration.

Ground magnetics (Figure 6) defines the magnetite alteration zone over an area of about 600m by 400 m. If smaller satellite magnetic anomalies to the east are included, it appears that the target area has a footprint of 1200 m by 400 m with a depth extent of approximately 200 m based on chargeability.

Item 12.4.2 Halilağa North

A total of 3.2 line kilometres of pole-dipole IP was conducted at Halilaga North, over 4 north-south oriented lines (Map 5).

A strong chargeability anomaly is indicated to a depth of 150 m and a width of approximately 400m on line 489000E (line 90, Figure 8). At surface, the chargeability anomaly is associated with a strong resistor which extends to 100m depth over a width of 100 m. These anomalies are strongest on the western most IP line (line 90) suggesting that sulphidic mineralisation may occur at depth to the west and under cover.

Item 13 Drilling

This report describes drilling undertaken between September 2007 and November 2007 (Table 2) within the Pirentepe and Halilağa areas. No drilling has been conducted at Halilağa North by Fronteer. Locations and local prospect geology are shown on Figures Spectra Jeotek of Ankara, Turkey was contracted to drill using a tractor mounted Delta Drill D-120 for HQ-NQ diamond core. During 2007, a total of 890.1 meters of drilling occurred in 10 holes on Pirentepe and a total of 298.2m meters of drilling occurred in one hole on Halilağa (Hole descriptions and summaries are shown in Appendices 1 to 5).

All drilling was supervised by Fronteer technical staff and general industry standards in all matters were followed.

All proposed drill collars were surveyed using a theodolite total station. Control was relative to established survey points across the property. Drills were set up under the direct supervision of Fronteer staff.

Drill holes were collared and drilled in HQ diameter core. Core was placed in plastic boxes with depth markers every drill run (up to 3 meters). Core recovery during these programs was generally adequate to good. Boxes were securely sealed and brought to the core facility in Sögütalan once a day by the Fronteer technical staff. Flexit survey tests were taken generally at 50-75 meter intervals down-hole to provide down hole survey control. All casing was attempted to be removed after drilling was completed, with only minor casing left stuck in the ground. Core logging procedures follow industry standards and a defined sample protocol.

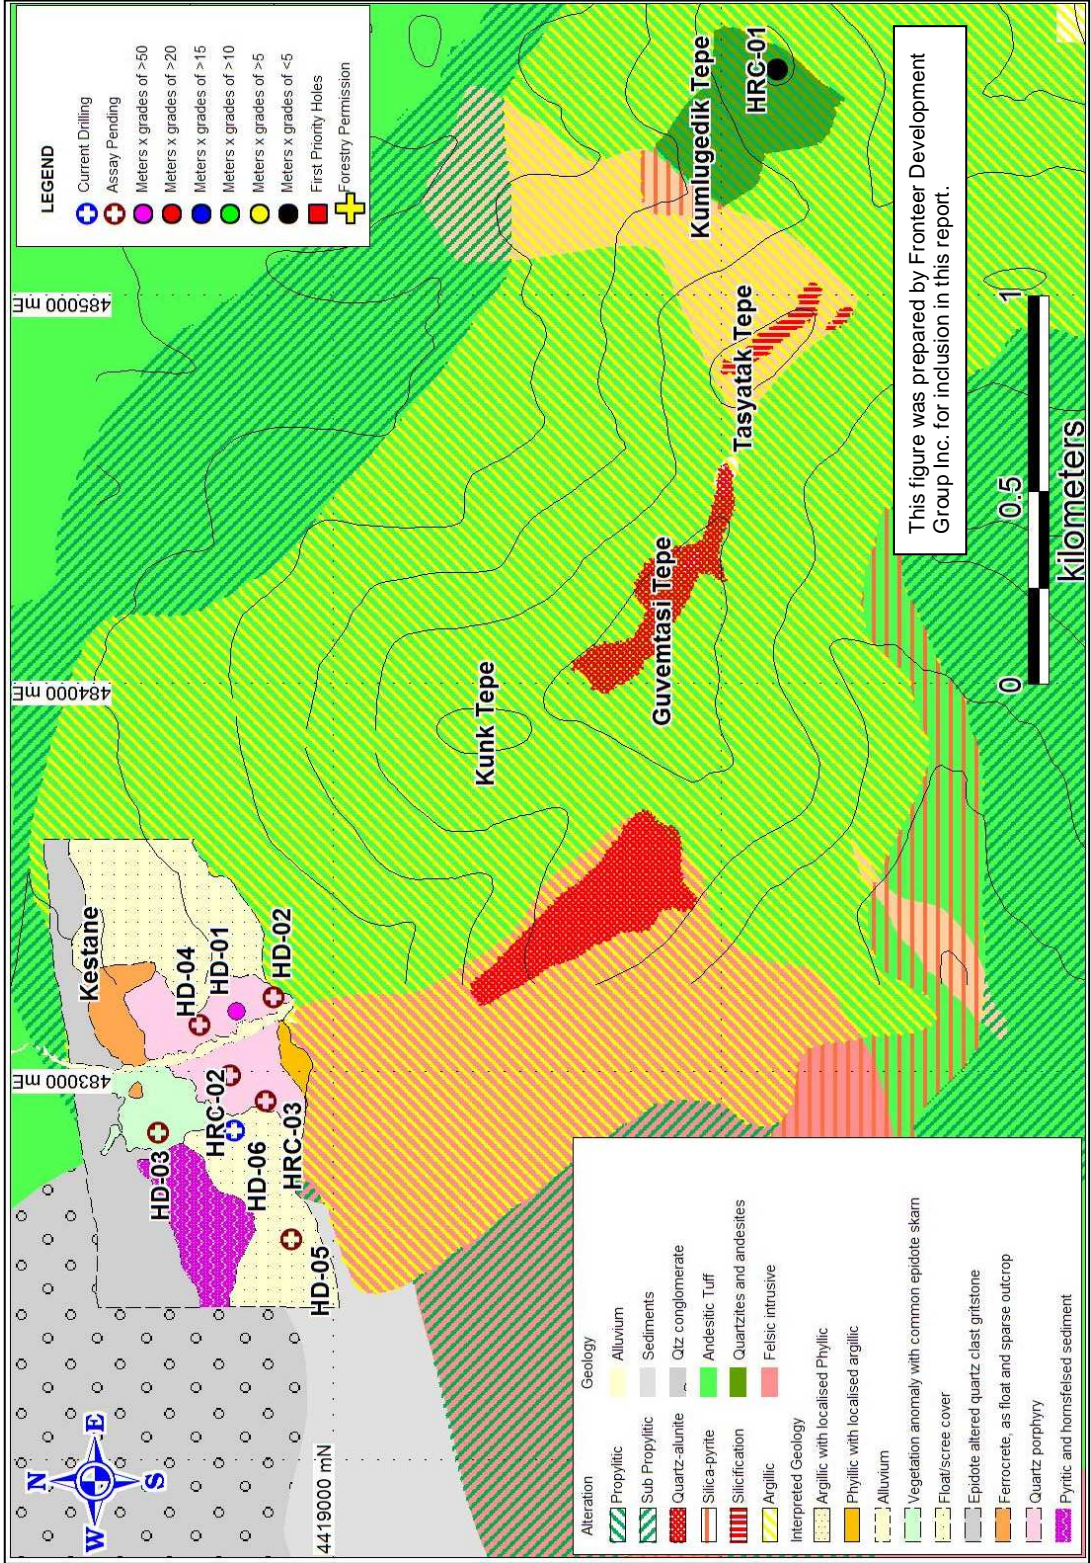

Figure 10 Drill hole location and geology, HD-01, Halilağa

Item 15 Sample Preparation, Analyses and Security

All drill core samples collected by Fronteer during drill programs on Pirentepe and Halilağa were subjected to a quality control procedure that ensured a best practice in the handling, sampling, analysis and storage of the drill core (Appendix 7). All drill holes were sampled and assayed continuously. Sample intervals were selected on a geological basis and most typically varied between 0.5 and 1.0 meters in length. Sample intervals were very rarely less than this (minimum 0.30 meters) on specific, narrow geological features, and rarely greater than 1.0 meters (maximum 1.5 meters) on wide intervals of un-oxidized rock. Core was cut lengthwise in half with half the core being submitted for assaying.

ALS Chemex Laboratories have analyzed all the rocks, soils, and core samples from the Pirentepe and Halilağa Projects (ALS Romania also analysed core samples from HD-01). They determined gold by fire-assay fusion with atomic absorption spectroscopy, as well as 34 elements by aqua regia acid digestion ICPAES (Appendix 8). For copper-rich samples at Halilağa a further analysis of to test the leachability of the copper are performed using different leaches and conditions and atomic absorption (aasay results are shown in Appendices 9 and 10).

Samples of drill core were cut by a diamond blade rock saw, with half of the core placed in individual plastic bags and sealed with a numbered tag. The other half of the core was placed back in the original core box. Samples were prepared by local contract labourers trained and supervised by Fronteer personnel at the Soğutalan core facility, near Çan.

Samples were shipped by an independent transport company in woven plastic bags for sample preparation to ALS-Chemex preparation laboratories in Izmir, Turkey. After these samples were processed, the pulps were sent by an independent transport to the ALS-Chemex lab in Vancouver, Canada for analysis. Rejects and pulps are stored onsite at the Sogultalan core shack.

Notification of receipt of sample shipments by the laboratory is confirmed by electronic mail. No problems were encountered in transport during the program.

Samples were prepared and processed at the ALS-Chemex preparation laboratories in Izmir, Turkey. After these samples were processed, the pulps were sent by an independent transport to Vancouver, Canada to the ALS-Chemex laboratory for analysis.

ALS Chemex laboratory is operated in accordance with the guidelines set out in ISO/IEC Guide 25 – “General requirements for the competence of calibration and testing laboratories”.

Sample preparation and analyses

Individual core samples typically ranged from 0.5 kg to 2 kg in weight. The entire sample was crushed to 2mm size in an oscillating steel jaw crusher. Approximately a 250g split is pulverized in a chrome steel ring mill. Coarse reject is bagged and stored. Pulps are shipped to Canada for analyses at ALS Chemex in North Vancouver.

Au was determined by fire-assay fusion of a 30 g sub-sample with atomic absorption spectroscopy.

Samples were analyzed for 33 elements (Ag, Al, As, B, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, Ga, Hg, K, La, Mg, Mn, Mo, Na, Ni, P, Pb, Sb, Sc, Sr, Tl, Ti, U, V, W, and Zn) by aqua regia digestion (ICP) atomic emission spectroscopy. Over limits of greater than 10, 000 ppm Cu, Pb, and Zn were determined by ore grade assay ICP analysis.

Results are reported electronically to the project site in Soğultalan with Assay Certificates filed and catalogued at Teck Cominco's Office in Ankara, Turkey.

Sample Quality Assurance data and Protocols

At the Pirentepe and Halilağa projects , inserting of “blind” quality control samples takes place in the core shack before samples are shipped to the lab. These samples inserted on a routine basis and are used to check laboratory quality and cleanliness. At the beginning of sampling, Sample tags are pre-marked with locations for standards, duplicates and blanks before logging.

Duplicates

Duplicate samples are taken every 20 samples within the sample series. Duplicate samples are used to monitor sample batches for potential mix-ups and monitor the data variability as a function of both laboratory error and sample homogeneity. The duplicate samples are ¼ spilt cores done on site before the sample leaves camp.

Blanks

Un-mineralised limestone was used as a blank, where material was collected from an outcrop in camp, broken with a hammer and inserted into the sample series every 20 samples.

Standards

Standards are used to test the accuracy of the assays, and to monitor the consistency of the laboratory. They are needed for documentation at the time of ore reserve calculations. Standards were bought from CDN Resource Laboratories Ltd. These standards were randomly inserted into the sample sequences every 20 samples.

Check Samples

5% of all assayed sample pulps are being sent to a second laboratory for analysis. This approach identifies variations in analytical procedures between laboratories, possible sample mix-ups, and whether substantial biases have been introduced during the course of the project.

Results of the standards and the blanks are checked and reviewed quickly after results are received. Control charts are used to monitor the data and decide immediately whether the results are acceptable.

QA/QC Analyses – Pirentepe and Halilağa

Standards were used to test the accuracy of the assays and to monitor the consistency of the laboratory. The standards used were bought from CDN Resource Laboratories Ltd. These standards were randomly inserted into the sample sequences approximately every 20 samples.

A total of 61 standards were analyzed during the 2007 Pirentepe Drill Program (Table 3). The results of these analyses are presented in Figure 8 and generally fall within the accepted range of 2 standard deviations.

| Standard | Gold concentration | # Used |
|----------------------|---|--------|
| CDN-GS-2A | Gold concentration: 2.04 ± 0.19 g/t | 19 |
| CDN-GS-2B | Gold concentration: 2.03 ± 0.14 g/t | 14 |
| CDN-GS-5B | Gold concentration: 4.83 ± 0.38 g/t | 1 |
| CDN-GS-P3 | Gold concentration: 0.30 ± 0.04 g/t | 35 |
| CDN-GS-P5 | Gold concentration: 0.525 ± 0.042 g/t | 10 |
| Total Standards Used | | 79 |

Table 4 List of Standards used at the Pirentepe Project

Figure 11 Standards Results – Pirentepe and Halilağa CDN Data

Blanks

Blanks are generally used to check the cleanliness of the laboratory and should produce negligible gold results on a consistent basis. A crushed clean limestone was bought and inserted randomly into the sample series every 20 samples.

A total of 60 blanks were analyzed during the 2007 Drill Program. The results of these analyses are presented in Figure 9. The results were all less than 0.020 g/t Au.

Figure 12 Blank Results – Pirentepe and Halilağa

Duplicates

Duplicate samples are used to monitor sample batches for potential mix-ups and monitor the data variability as a function of both laboratory error and sample homogeneity. The duplicate samples are ¼ spilt cores done on site before the sample leaves camp. Duplicate field samples are taken every 20 samples within the sample series.

A total of 64 field duplicates were analyzed during the 2007 Drill Program. The results of these analyses are presented in Figure 10 and fall within acceptable limits.

Figure 13 Duplicates Results – Pirentepe and Halilağa

Analysis of the above data indicates that there were no QA/QC issues with analyses.

Check Assays

A protocol has just been initiated to send 5% of all assayed sample pulps to a second laboratory for analysis. This approach identifies variations in analytical procedures between laboratories, possible sample mix-ups, and whether substantial biases have been introduced during the course of the project. This work is taking place at Acme Analytical Laboratories in Vancouver. Final analyses of these samples should be received in early March.

No QA/QC problems are noted at this time. The samples surrounding the few standards which failed more than three standard deviations have been re-sent to ALS-Chemex for reanalysis.

The author is not aware of any aspect of the sample preparation was conducted by an employee, officer, director or associate of the issuer, with the exception the likely occurrence of some rock chip sampling being undertaken by employees of Fronteer.

The author is not aware of any factors in the sampling procedures that could materially impact the accuracy/reliability of the mineral resource and mineral reserve estimates set forth in this Report. The sample checks have demonstrated that the samples are representative of the mineralization and that there is no bias in the sampling.

Item 16 Data Verification

The author has partially verified the analysis data related to the drilling of holes PD-01 to PD09 and HD-01. Verification was undertaken by spot checking of laboratory generated Certificates of Analysis against the tabulated data. Some data has not been verified as final Certificates of Analysis have not yet been prepared. Geophysical field data was not verified and the author has relied on the information presented in the geophysical report supplied by Fronteer (see also the disclaimer) for the purposes of this report.

Item 17 Adjacent Properties

Two adjacent properties (as a result of contiguous permit holdings) contain significant mineralisation, The Kırazlı project located approximately 10 km to the north of Pirentepe, and the Aği Dağı property approximately 15 km to the east of Halılağa (see Figure 1).

The information provided below is sourced from NI43-101 reports and press releases prepared for, or by, Fronteer. These documents refer to information prepared by Qualified Persons (not the author of this report) contained within referenced NI43-101 Technical reports. The author has undertaken field visits to both the Kırazlı and Aği Dağı properties, but has not prepared any report, interpretation, or recommendation for them.

The author has been unable to verify the information contained in the press releases and **the information is not necessarily indicative of the mineralization on the properties that are the subject of this technical report.**

For clarity, this technical report describes the mineralisation and exploration conducted on the Halılağa and Pirentepe properties and apart from inclusion of the results of exploration from the adjacent Kırazlı and Aği Dağı it does not relate to the adjacent properties.

The author understands that the estimates of mineral resources and mineral reserves described in the publicly available information related to the adjacent properties has been prepared and disclosed in accordance with section 2.4 of the Instrument.

Kirazlı

Fronteer (Cunningham-Dunlop IR and Giroux G, 2006) describe the Kirazlı property as lying within the Eocene to Pliocene-age, calc-alkaline to alkaline Çanakkale volcanic field. The property is underlain by a sequence of andesitic to dacitic porphyritic coherent and clastic volcanic rocks whose primary textures are largely obscured by a blanket of intense silica and clay alteration. Gold mineralization on the property reflects a high-sulphidation epithermal system. Early-phase alteration resulted in an upper layer of dense silicification overlying argillized, pyritic alteration. This is cut by a series of fluted phreatic breccias that provide conduits to silica-, sulphide-, gold- and silver-bearing fluids that pooled beneath the dense silicified and are haloed by advanced argillic alteration.

The property was the subject of considerable exploration work by a previous operator from 1987 to 1992 which culminated in drilling 25 percussion holes (563.54m), 20 reverse circulation holes (3,373.46 m), and 24 diamond drill holes (3,274.50m). A shallow-dipping zone of high-grade mineralization was discovered immediately below the barren silica cap in a number of holes and returned results up to 5.0 g/t gold over 52.5 metres, 13.7 g/t gold over 19.5 metres, 1.9 g/t gold over 103.5 metres, and 3.64 g/t gold over 61.50 metres.

From February to December 2005, Fronteer completed an exploration program that involved 7385.6 m of diamond drilling in 44 holes, 30 km of line cutting, 30 line km of induced polarization geophysics, four metres of trenching, 1:2000 scale bedrock mapping and the collection and analysis of 634 soil samples, 167 grab samples and 64 channel samples. This program expanded the known high-grade zone, delineated a deeper high-grade feeder zone (5.7 g/t gold over 51.2 metres, including 16.62 g/t gold over 15.3 metres), identified and confirmed significant local silver mineralization (27g/t silver over 117 metres and 89 g/t silver over 64 metres), identified areas of drill-ready surface mineralization and improved on the understanding of the geology and of the geometry of mineralized zones.

In a press release dated November 20, 2006, (<http://www.fronteergroup.com/sweetspot-cont-00.htm>) Fronteer announced new drilling results from the Kirazlı property. Drill hole

KD-57 intersected a broad interval of gold mineralization that returned 2.00 grams per tonne gold over an aggregate length of 135.5 metres including three separate mineralized zones as follows:

- 4.42 grams per tonne gold over 6.6 metres starting at a depth of 40 metres.
- 1.6 grams per tonne gold over 12.75 metres starting at a depth of 93 metres.
- 11.02 grams per tonne gold over 15.2 metres starting at 183 metres.

Drill hole KD-57 was reported as one of three new holes that tie together economically significant gold mineralization near the south-eastern margin of the 2005 resource area. The other two holes identified earlier in 2006 were KD-48 (2.86 grams per tonne gold and 144.2 grams per tonne silver over 21.0 metres) and KD-54 (1.0 grams per tonne gold over an aggregate length of 160.8 metres).

Other additional new significant gold intersections include:

- Drill Hole KD-62, which intersected 0.62 grams per tonne gold over 158.7 metres including 1.22 grams per tonne gold over 10.5 metres on the western margin of the resource area.
- Drill Hole KD-64, which intersected 0.98 grams per tonne gold over 103.8 metres including 2.00 grams per tonne gold over 16.5 metres on the northern margin of the resource area.

The current resources at Kirazlı (as at the date of the Press Release, 20 November, 2006) and as reported by Fronteer (Cunningham-Dunlop IR, and Giroux G, 2006) include 5,430,000 tonnes @ 1.40 g/t gold for an Indicated Resource of 244,000 ounces and 17,810,000 tonnes @ 0.98 g/t gold for an Inferred Resource of 563,000 ounces. The silver resources include 5,430,000 tonnes @ 9.70 g/t silver for an Indicated Resource of 1,693,000 ounces and 17,810,000 tonnes @ 6.74 g/t silver for an Inferred Resource of 3,859,000 ounces. The resource area on Kirazlı was reported as open for expansion to the north and south and at depth.

The Independent Qualified Person responsible for the preparation of these resource estimates was Gary Giroux, P. Eng. of Giroux Consultants Ltd. and is contained in a Technical Report prepared to NI43-101 requirements (Cunningham-Dunlop IR, and Giroux G, 2006).

Aği Dağı

Fronteer released details of drilling on the adjacent Aği Dağı property on January 9, 2007 and September 26, 2006 (<http://www.fronteergroup.com/newsroom.htm>). The abridged press releases are given below.

Fronteer that five drill rigs were operating at Aği Dagi, and were focused on expanding the 2006 resource areas, as well as testing additional targets for new discoveries. In total, 16,357 meters of drilling was completed at Aği Dağı in 2006.

Deli Zone

Four new drill holes from the Deli Zone continue to demonstrate that this resource area remains open for expansion. In particular:

- Drill hole AD-230 intersected 1.41 grams per tonne gold over 60.20 metres, including 5.55 grams gold per tonne over 11.00 metres. This intersection is interpreted to be a continuation of the same zone that was intersected 116 metres to the east of AD-212, which returned 3.96 grams per tonne gold over 111.3 metres.

Other new significant intersections from the Deli Zone include:

- 0.91 grams per tonne gold over 24.00 metres, including 1.21 grams per tonne gold over 15.00 metres from hole A-218, a hole outside the southeast limit of the 2006 resource area.
- 0.71 grams per tonne gold over 16.35 metres, including 1.06 grams per tonne gold over 8.40 metres from hole AD-222.
- 0.80 grams per tonne gold over 17.60 metres including 1.15 grams per tonne gold over 9.95 metres from hole AD-211, a hole outside the northern limit of the 2006 resource area.

Firetower

Firetower is a new target area located approximately 1.5 kilometres to the southwest of the Deli Zone. Significant results intersected at Firetower are:

- gram per tonne gold over 11.10 metres from hole AD-214
- 0.82 grams per tonne gold over 8.75 metres from hole AD-232
- 1.15 grams per tonne gold over 14.90 metres from hole AD-136
- 1.14 grams per tonne gold over 7.50 metres from hole A-143

Fronteer reported that the orientation of mineralized zones is variable but true widths are estimated to be 90 percent of those stated.

Earlier, Fronteer released the following results. Drill hole (AD-212) located 150 metres to the west of the current Deli Resource Area has intersected 3.96 grams per tonne gold over 111.3 metres, including 7.1 grams per tonne over 15.0 metres and:

- 2.78 grams per tonne gold over 8.00 metres and 2.15 grams per tonne gold over 6.15 metres from hole AD-210
- 1.0 gram per tonne gold over 37.5 metres from hole A-215
- 5.42 grams per tonne gold and 31.17 grams per tonne silver over 9.60 metres from hole AD-183
- 3.21 grams per tonne gold over 7.25 metres from hole AD-178
- Drill hole A-179 intersected several distinct gold-silver zones including:
- 0.57 grams per tonne gold over 22.50 metres
- 0.75 grams per tonne gold and 54.68 grams per tonne silver over 15.20 metres
- 0.66 grams per tonne gold and 53.81 grams per tonne silver over 21.20 metres

Hole A-191 tested a new target area located 850 metres away from the Deli Resource Area and intersected 0.58 grams per tonne gold over 51 metres.

Fronteer reported the current resource at Agi Dağı Project consists of two main resource areas and numerous target zones developed within a 4 kilometer-long north-west

trending zone of alteration. The grade, tonnage and classification of the resource estimates from Agi Dagi were reported as 7,800,000 tonnes at 0.86 g/t Au and 1.60 g/t silver for 178,000 ounces of gold and 179,000 ounces of silver in the indicated category. The inferred category contains 34,780,000 tonnes at 0.93 g/t gold and 4.2 g/t silver for a total for 1,043,000 ounces of gold and 4,697,000 ounces of silver.

Item 18 Mineral Processing and Metallurgical Testing

No mineral processing or metallurgical test work has been undertaken on the properties referred to in this report. These activities will be undertaken at an appropriate stage in the work programme.

Item 19 Mineral Resource and Mineral Reserve Estimates

As the properties referred to in this report are at a relatively early stage of exploration, no mineral resource or reserve estimates have been conducted. These activities will be undertaken at an appropriate stage in the work programme.

Item 20 Other Relevant Data and Information

The author is not aware of any additional information necessary to make the technical report more understandable, nor is he aware of any omissions or inclusions that could be misleading.

Appendix 6 contains a glossary of terms used in this report.

For clarity the following is included. In Turkey underground resources are subject to the exclusive ownership and disposition of the State and are not considered part of the land where they are located. Under the mining legislation, the state delegates its right to explore and operate mines to individuals or companies for specific periods by issuing licenses subject to payment of a royalty to the State.

Certain provisions of Turkish Mining Law were recently amended in 2004. The pre-operation license provided by the old law was repealed. The basis of royalty payments to the State has been changed to a percentage of total sales. Mining activities conducted within state-owned lands will be subject to an additional 30% royalty.

Item 21 Interpretation and Conclusions

The Halilağa, Halilağa North, and Pirentepe prospects are located in the south central part of the Biga Peninsula in Western Turkey. Basement rocks of the Biga Peninsula consist of Paleozoic metamorphic rocks and Mesozoic mélanges of eglocites, clastic and carbonate lithologies. Examples of these lithologies occur within, or immediately outside the mapped areas. Granitic and granodiorite intrusives cut the basement rocks and are overlain by cal-alkaline and alkaline volcanics ranging in age from 35-23 Ma. A Miocene andesitic volcanic suite includes andesite, latite, dacite, rhyodacite lava dome facies, and volcanoclastic sequences including ignimbrites and is related to partial melting of the crust during N-S compression and crustal thickening, and later extension. At Halilağa, Halilağa North, and Pirentepe, the andesites are interpreted to be volcanic to sub-volcanic, with an overlying and intercalated sheet, or sheets, of varying tuff units, now present only as silicified cap remnants at higher elevations.

The Pirentepe and Halilağa prospects are interpreted to be a single widespread mineralised system containing porphyry related high-sulphidation style gold and copper-gold mineralisation. Halilağa North is interpreted to be a structurally controlled high-sulphidation system distal to a high level intrusive. The mineralised intrusives are interpreted to be related to the 35-23 Ma granites and granodiorites.

Drilling by Fronteer at **Pirentepe** returned the following results:

- PD-01 intersected 1.79 grams per tonne gold over 46.90 metres, starting at 17 metres depth. The hole ended in high-grade gold mineralization.
- PD-02 intersected 1.83 grams per tonne gold over 38.0 metres also starting at 17 metres.

Further drilling is required to define the limits and orientation of the mineralisation which is hosted in pyritised andesitic tuff sediments. Lacustrine sediments are mapped up to 2 km from the known mineralised zone indicating potential for discovery of more pyritised sediments in fault depressions. Mineralised intersections given above may not indicate the true width.

Porphyry copper-gold mineralisation at the **Central Zone** within the **Halilağa** property has been identified in the newly discovered Central Zone. Mineralization occurs over the full length (298.2 m) of the first drill hole in this area (HD-01). Drill hole HD-01 intersected:

- 0.50 grams per tonne gold and 0.53% copper over the entire length of 298.2 metres, including 1.03 grams per tonne gold and 1.03% copper over 105.4 metres. Both intervals start from surface.
- A thick zone of secondary copper enrichment returned 2.15% copper and 0.93 grams per tonne gold over 25.8 metres starting at a depth of 23.8 metres.

HD-01 was collared in the central part of Central Zone in oxidized feldspar-quartz porphyry with a stockwork of 25-30% quartz veins to 23.95m. The supergene acid leach alteration zone, with 10% veining, 2% pyrite veins and chalcocite on fractures was intersected from 23.95-55.0m. Below the supergene alteration, the vein stockwork increases to 35-50% with 5-15% magnetite, 2-5% pyrite, >2% chalcopyrite and minor chalcocite and molybdenite. This veining mostly obliterated the original intrusive texture. A fault was intersected from 98.2-99.3m. Below the fault, the feldspar-quartz porphyry was potassic altered with sericite-magnetite-biotite-quartz, with zones of silica flooding and quartz veins varying from 8-40%, 2-5% pyrite and 0.5-1% chalcopyrite to about 154.2m. Below this the core have mostly biotite>magnetite alteration and usually >5% quartz veining; with zones of pink potassic alteration and few silica flooded zones. Pyrite veins and minor chalcopyrite was seen throughout the hole. From 286-298.2m, the hole ended in a siliceous green diorite.

At Halilağa 39.5 line kilometres of IP Chargeability/Resistivity and 43.5 line kilometres of ground magnetic surveying was conducted. The most significant anomaly generated is the coincident chargeability magnetic anomaly associated with the Central Zone porphyry copper-gold mineralisation intersected by hole HD-01.

The IP chargeability profile across the Central Zone (Line 8) shows a chargeability anomaly associated with the mineralised quartz porphyry centred on station 1400N with a depth profile in excess of 200 m.

Ground magnetics defines the magnetite alteration zone over an area of about 600m by 400 m. If smaller satellite magnetic anomalies to the east are included, it appears that the target area has a footprint of 1200 m by 400 m with a depth extent of approximately

200 m based on chargeability. The Central Zone has potential for copper-gold mineralisation to extend to the limits of the geophysical anomalies.

At **Halilağa North** Rock chip sampling has defined a strongly gold anomalous trend over 1000 m by 200 m oriented in a ENE direction, immediately north of the village of Halilağa. The highest grade rock chip sample was 1.24 g/t Au. Soil sample anomalies confirmed this trend and returned a peak gold result of 91 ppb Au. A strong chargeability anomaly is indicated to a depth of 150 m and a width of approximately 400m on line 489000E (line 90, Figure 8). At surface, the chargeability anomaly is associated with a strong resistor which extends to 100m depth over a width of 100 m. These anomalies are strongest on the western most IP line (line 90) suggesting that sulphidic mineralisation may occur at depth to the west and under cover.

Item 22 Recommendations

Continued exploration is warranted on the Pirentepe, Halilağa and Halilağa North prospects properties. In-fill geophysical surveys (IP Gradient Array, Dipole-dipole IP as well as detailed ground magnetics) should be conducted over the known targets (Davulgalı Tepe PD-01 and PD-02 Pirentepe), Central Zone (HD-01 Halilağa), and Halilaga North.

Successful definition of targets by geophysical surveys and the current drill programme will result in a decision point to undertake further drilling.

A proposed budget for the next two stages of exploration (infill geophysics and drilling) at Pirentepe (1800 m RC drilling), Halilağa (central Zone - 2400m RC and 3000m core), and at Halilağa North is set out below in Table 4.

| | Pirentepe 1800 m RC drilling | | Halilağa (Central Zone) 2400m RC and 3000m core drilling | | Halilağa North 1200 m RC drilling | |
|---------------------------------------|------------------------------------|---------------|--|---------------|--|---------------|

I, *Peter Grieve M.Sc. M.A.I.G.*, do hereby certify that:

1. I am a Consultant Geologist and Director of:

Geology and Resource Solutions Limited
PO Box 24, Alexandra, Otago, New Zealand 9340
2. I graduated with a Bachelor of Science degree from the University of Auckland in 1985. In addition, I have obtained a Master of Science degree in Geology from the University of Auckland in 1987.
3. I am a member of the Australian Institute of Geoscientists.
4. I have worked as a geologist for a total of 20 (twenty) years since my graduation from university.
5. I have read the definition of "qualified person" set out in National Instrument 43-101 ("NI 43-101") and certify that by reason of my education, affiliation with a professional

association (as defined in NI 43-101) and past relevant work experience, I fulfill the requirements to be a "qualified person" for the purposes of NI 43-101.

6. I am responsible for the preparation of all sections of the technical report titled NI43-101 TECHNICAL REPORT ON THE PIRENTEPE AND HALILAĞA EXPLORATION PROPERTIES, ÇANAKKALE, WESTERN ANATOLIA, TURKEY Prepared for Fronteer Development Group Inc. Suite 1650 – 1055 West Hastings Street Vancouver, B.C. V6E 2E9 and dated March 30, 2007 (the "Technical Report") relating to the PIRENTEPE AND HALILAĞA properties. I visited the properties during July to September 2005 (Pirentepe), July 2006 (Halilağa North) and July-August 2006 (Halilağa). Selected drill core from both properties was reviewed during early December 2006 including holes PD-01, 02, and HD-01.
7. I have not had prior involvement with the property that is the subject of the Technical Report.
8. I am not aware of any material fact or material change with respect to the subject matter of the Technical Report that is not reflected in the Technical Report, the omission to disclose which makes the Technical Report misleading.
9. I am independent of the issuer applying all of the tests in section 1.5 of National Instrument 43-101.
10. I have read National Instrument 43-101 and Form 43-101F1, and the Technical Report has been prepared in compliance with that instrument and form.
11. I consent to the filing of the Technical Report with any stock exchange and other regulatory authority and any publication by them for regulatory purposes, including electronic publication in the public company files on their websites accessible by the public, of the Technical Report.

Dated this 30th Day of March, 2007

Appendix 1 Pirentepe drill hole summaries

Drill Hole: PD-01

Target Location: 50m away from MJTC-2, testing breccia corridor and continuation of mineralization

Geologist: Brenda Hodgins

Date: Sept 23, 2006

Location: 479594E, 4420921N Az: 140 Dip: - 60

| From | To | Description |
|------|------|--|
| 0 | 1.5 | Overburden (Casing to 4.2m) |
| 1.5 | 4.5 | Andesite Tuff w/ chalcedonic alteration |
| 4.5 | 13.0 | Silicified Andesite Tuff w/ limonite and clay on fractures |
| 13.0 | 19.6 | Quartz-Clay Altered Andesite Tuff w/ local breccia and oxides on fractures |
| 19.6 | 22.9 | Argillic Altered Rhyolite - oxide |
| 22.9 | 27.3 | Intense limonite-hematite fractured rhyolite w/ local silicified breccia |
| | EOH | |

Additional Notes:

Current depth/total depth is 27.3 /150m

Drill Hole: PD-02

Target Location: Twin of MJTC-2, testing breccia corridor and continuation of mineralization

Geologist: Ssercan Bozan/Brenda Hodgins

Date: Sept 26, 2006

Location: 479594E, 4420921N Az: 220 Dip: - 50 FINAL DEPTH 95.1m

| From | To | Description |
|------|------|--|
| 0 | 2.30 | Overburden (casing to 3 m) |
| 2.30 | 3.60 | Dark grey color, Andesitic tuff with chalcedonic alteration |
| 3.60 | 8.80 | Beige color, strongly-silicified, hematite rich through the fractures in (Qtz-feld-porphyry) Rhyolite |
| 8.80 | 21.5 | Beige color, Quartz -clay altered Rhyolite with local breccia and oxide on abundant fractures |
| 21.5 | 37.8 | Orange-red limonite-rich clay with 20% rounded silicified rhyolite clasts |
| 37.8 | 41.2 | Creamy rhyolite blocks in grey siliceous sandy-clay |
| 41.2 | 48.7 | Strong limonite>hematite oxidized rhyolite with abundant clay |
| 48.7 | 55.6 | More competent crackle breccia of silicified rhyolite with oxide-rich matrix and fractures |
| 55.6 | 61.3 | Black volcanic tuff with 5-10% fine-grained pyrite and possible graphite |
| 61.3 | 85 | Argillic altered sulphidic volcanic, probably a feldspar-hornblende porphyry. |
| 85 | 95.1 | Weak chlorite altered plag-hbl porphyritic volcanic tuff |
| | EOH | |

Additional Notes:

Current depth/total depth 95.1m

Drill Hole: PD-03 (Site L26-P3)

Target Location: *Resistivity high on the flank of chargeability high; soil and rock Au anomalies and silica cap.*

FINAL DEPTH: 298.2 M

Appendix 3 Summary Hole Descriptions – Pirentepe and Halilağa

Drill Hole Summaries - Pirentepe

PD-01 (Az 140°Dip -60/Total Depth – 64.0m) Hole PD-01 was collared at the same location as historical hole MJTC-02, but drilled at 140° degrees instead of 220°, to test the interpreted structural corridor. This hole intersected chalcedonic and strongly silicified rhyolites to 13m, followed by strongly limonitic quartz-clay altered rhyolite with localized breccia to 19.6m. Argillic and intensely oxidized rhyolites followed to 27.8m, after which silicified rhyolite was encountered to 31m. Strongly argillic altered limonite-hematite volcanics were intersected to the redox boundary at 43m. Strong grey argillic clay altered volcanics were seen to 49.4m, followed by layered volcanic ash to lithic tuffs with up to 15% pyrite locally in layers. The last two meters of the hole intersected a fine grained ash tuff, with less than 5% pyrite. The rods were stuck in the hole at 64m, and when they got them out, it was decided to turn the drill and recollar as PD-02 twinning the historical hole.

Gold assays received from this hole included 1.83 g/t Au over 46.9m including 3.89 g/t Au over 8.8m.

PD-02 (Az 220°Dip -50/Total Depth – 95.1m) Hole PD-02 is collared on the same set-up as PD-01 to twin the historical hole MJTC-02 which interested >100 ppb gold in a limonitic argillic-silica altered zone from 18.00 m to 54.20 m. This zone averaged 700 ppb gold over 36.20 m. In addition silver, mercury and antimony are elevated over this zone (9.3 ppm Ag, 2400 ppb Hg, and 180 ppm Sb). Peak gold value in this hole is 3 m at 4400 ppb from 48 to 51 m.

PD-02 intersected the same package of rocks with chalcedonic and strongly silicified rhyolites to 8.8m, followed by strongly limonitic quartz-clay altered rhyolite with localized breccia to 21.5m. From 21.5m to 48.7m, an orange-red limonite-hematite-rich clay with 20% rounded silicified rhyolite clasts was intersected. Below this a more competent crackle breccia of silicified rhyolite with oxide-rich matrix and fractures, was encountered to the redox boundary at 55.6m. From 55.6-61.3m, a dark volcanic tuff with 5-10% fine

grained pyrite was followed by argillic altered feldspar-hornblende porphyry. From 85m to the end of the hole a dark grey-green weakly chloritic plagioclase-hornblende porphyritic volcanic tuff was seen.

Gold assays received were 1.83 g/t Au over 38.0m including 2.34 g/t Au over 14m and another 2.25 g/t Au over 11.3m

PD-03 (Az 00°Dip -80/Final Depth – 58.5m) Hole PD-03 was drilled to test a resistivity high at the flank of chargeability high. Few soil and rock gold anomalies in the area. This hole was a disappointment intersecting silicified andesite tuff to 4.6m, followed by silicified andesite breccia with a hematitic-clay matrix to 8.0m. After 8.0m, the rock became argillic clay altered feldspar porphyry with the redox boundary intersected at 13.3m. No significant gold assays were intersected in this hole.

PD-04 (Az 00°Dip -90/ Final Depth – 146.4m) Hole PD-04 was drilled to test the centre of largest resistivity high. This hole intersected a large layered moderately silicified andesite tuff package to 40.5m, after which the same geological unit became more quartz-clay altered to 60.2m. The andesitic crystal tuff then became argillic clay altered to 67m, after which the hole intersected weak to moderately silicified andesite with hematite-limonite-clay filled fractures and some oxidized clay zones (possible fault gouge) to 81.4m. It then became moderate to pervasively silicified ash to crystal layered rhyolitic tuff with oxides along fractures to 106.2m. Below this a dark pervasively silicified rhyolitic tuff with abundant oxide-rich fractures exists until it intersects a fault gouge from 107.9-108.4m. From 108.4-115.4m, a pervasively silicified and locally chalcedonic andesite tuff is intersected with strong hematite>limonite rich clay on fractures. At 115.4m, silicified feldspar porphyry with small unoxidized islands surrounds a small fault gouge from 118.8-119.2m. Below 122.2m, the feldspar porphyry is argillic altered to the end of the hole, and intersects the redox boundary at 127.95m. No significant gold assays were intersected in this hole.

PD-05 (Az 180°Dip -60/ Final Depth – 134.7m) Hole PD-05 was drilled to test a resistivity high and the flank of chargeability high. This hole is a 200m set-out from PD-04. This

hole intersected argillic feldspar porphyry to 11.7m, followed by a quartz-clay altered feldspar porphyry to 14.2m. The large package of layered andesitic crystal to ash tuff was then intersected to 55.9m, with two meters of jigsaw brecciation at the top of the unit. A coarse andesitic boulder breccia (part of the above volcanic package) was intersected to 62.6m, after which moderately silicified andesitic crystal tuff was intersected to 66.3m. A fault gouge from 66.3-66.9m separates the volcanic from the strongly oxidized and quartz-clay to argillic altered feldspar porphyry to the 79.4m. From 79.4-117.1 a moderately argillic altered feldspar porphyry changes repeatedly from oxide to sulphide. From 117.1-122.3m, a zone with 75 cm silica hydrothermal breccia is centred by buff white clay and further out two haematic fault zones. Below this a strongly argillic altered feldspar in intersected with the redox boundary at 127.1m. No significant gold assays were intersected in this hole.

PD-06 (Az 180°Dip -60/ Final Depth – 44.3m) Hole PD-06 was drilled to test a high resistivity near one of the properties silica pits. This hole was disappointing as we collared next to a silica rib but intersected no silica in the hole. The whole hole intersected moderate to strongly clay argillic alteration in feldspar +/- hornblende porphyry with good porphyritic texture preserved throughout. The redox boundary was located at 30.7m depth. No significant gold assays were intersected in this hole.

PD-07 (Az 180°Dip -60/ Final Depth – 104.5m) Hole PD-07 was drilled to test a resistivity high at the top of the silica cap. Few soil and rock gold anomalies in the area. This hole was a disappointment because although it was collared next to a silica rib, the hole intersected mostly argillic altered feldspar+/-quartz+/-hornblende porphyry from the collar. This hole did have a large amount of pyrophyllite filled late veins and fractures. This hole returned no significant gold results.

PD-08 (Az 00°Dip -90/ Final Depth – 37.1m) Hole PD-08 was lost because of stuck drill rods at 37.1m, but intersected quite different mineralization then it's twin hole PD-08A (1m away). This hole was collared to test the continuity of the anomalous zone intersected in holes PD-01 and PD-02 approximately 125m to the west. This hole was

collared in weak argillic altered feldspar porphyry to 13.1m, where it intersected a silicified, patchy oxide/sulphide, semi-massive sulphide feeder with aphanitic pyrite to 19.0m. From 19.0-19.8m, a vuggy silicified oxidized feldspar porphyry was intersected. Below this the core returned to oxidized weakly argillic altered feldspar porphyry, to the next silicified pyritic feeder intersected from 22.2-23.5m, with microbreccia zones with jarosite. From 23.5-32.7, the core re-entered the weak to moderately argillic altered feldspar porphyry, with the redox boundary at 27.5m. From 32.7- 37.1m (EOH), another siliceous feeder was intersected with 20% aphanitic pyrite. This hole was lost because of stuck rods and redrilled as PD-08A. This hole intersected 0.3 g/t Au over 4.4m to the end of the hole.

PD-08A (Az 00°Dip -90/ Final Depth –88.9m) Hole PD-08A is the re-drill of PD-08. From the collar to 13.9m, weak to moderate argillic altered feldspar porphyry was only cut by one vuggy silicified band from 10.5-11.2m. From 13.9-16.9m, moderate to strongly silicified oxidized feldspar porphyry was intersected. After this the feldspar porphyry was moderate to strongly argillic altered with locally abundant pyrophyllite veins to 33.6m, with the redox boundary at 26.8m. From 33.6-34.9m, a clay gouge was intersected. From 34.9-42.1m, a pyritic (15-30% pyrite) silicified volcanic rock was intersected with a 65cm fault gouge in the centre. The core then returned to moderate to intensely altered feldspar hornblende porphyry to 71.1m. From 71.1-75.2m, another silicified volcanic containing 20-25% fine-grained pyrite. Below this the core still had 10% pyrite but was argillic altered to 76.8m. The last interval to 88.9m, was an argillic altered feldspar hornblende porphyry. No significant gold assays were intersected in this hole.

PD-09 (Az 00°Dip -45/ Final Depth – 116.6m) Hole PD-09 intersected argillic altered feldspar porphyry with minor silica clasts breccias to 22.8m. From 22.8-23.5m, a jarosite matrix and silica clast breccia was intersected. After this core hole stayed in feldspar porphyry with weak to pervasive argillic alteration with alternating zones of sulphide and oxides to the redox boundary at 37.5m. Below the redox boundary the core remained argillic altered with mostly <2% disseminated pyrite except for 82.7-91.2m, where 5-10% pyrite was disseminated. No significant gold assays were intersected in this hole.

Drill Hole Summaries - Halilağa

- HD-01 (Az 00°Dip -60/ Final Depth – 298.2m) The first hole in the Central zone was targeted above the anomalous outcrops, in the centre of the mag high. This hole was collared in oxidized feldspar-quartz porphyry with a stockwork of 25-30% quartz veins to 23.95m. The supergene acid leach alteration zone, with 10% veining, 2% pyrite veins and chalcocite on fractures was intersected from 23.95-55.0m. Below the supergene alteration, the vein stockwork increases to 35-50% with 5-15% magnetite, 2-5% pyrite, >2% chalcopyrite and minor chalcocite and molybdenite. This veining mostly obliterated the original intrusive texture. A fault was intersected from 98.2-99.3m. Below the fault, The feldspar-quartz porphyry was potassic altered with sericite-magnetite-biotite-quartz, with zones of silica flooding and quartz veins varying from 8-40%, 2-5% pyrite and 0.5-1% chalcopyrite to about 154.2m. Below this the core have mostly biotite>magnetite alteration and usually >5% quartz veining; with zones of pink potassic alteration and few silica flooded zones. Pyrite veins and minor chalcopyrite was seen throughout the hole. From 286-298.2m, the hole ended in a siliceous green diorite.

Results from this hole include:0.50 grams per tonne gold and 0.53% copper over the entire length of 298.2 metres, including 1.03 grams per tonne gold and 1.03% copper over 105.4 metres. Both intervals start from surface. And, a thick zone of secondary copper enrichment returned 2.15% copper and 0.93 grams per tonne gold over 25.8 metres starting at a depth of 23.8 metres.

Appendix 4 Pirentepe photographs

Photo 1 View looking north-east of the geophysically resistive silica cap exposed at two elevations at Celdiren Tepe (higher level) and Dağtarla Tepe (lower elevation) at approximately 481500 E 4421500 N. The offset in elevation is attributed to extensional down-faulting along the 060 trending corridor of fracturing and brecciation on the southern margin of the Pirentepe prospect.

Photo 2 Bedded dacitic to rhyolitic tuffs in drainages south of Büyükdag Tepe in the central Pirentepe prospect area (approximately 480500 E 4421300 N). These tuffs demonstrate the sub aerial deposition of eruptive products from a volcanic centre. The high primary porosity of these units enabled siliceous fluids to permeate and silicify these tuffs preferentially. This early silicification event was a precursor to later O60 rending fracturing and brecciation, and mineralisation (e.g. at Davulgali Tepe).

Photo 3 Shallow dipping silicified fine grained sediments deposited in a sub aqueous setting overlying intensely argillic altered porphyry intrusive. These sediments likely deposited in small lakes formed within extensional basins within the north-east trending inferred graben structure at Hacidevisler (approximately 477750 E 4422800 N). The silicified sediments lack some key indicators to be called sinter, e.g. anomalous Hg, oriented plant clasts, silica falls developed on the sinter edge but do contain sedimentary bedding and fragments of silicified wood.

Photo 4 Chalcedonic to opaline silica veining exposed along the north-western margin of a north-east trending inferred graben structure at Hacidevisler (approximately 477750 E 4422800 N). This silica veining is interpreted to be developed on northeast trending extensional structures and developed at a near surface (within or immediately below the paleowater table) epithermal setting.

Photo 5 Breccia textures from within the 060-080 trending inferred structural corridor SW Pirentepe (approx 480100E 4420900N). Clasts are silicified porphyry with hematitic rims, sometimes as specularite, and a later dusty hematite coating. Voids within the hematite can be in filled with fine banded chalcedony indicating a late silica event.

Photo 6 Weak to moderate propylitically altered feldspar-quartz-hornblende altered porphyritic intermediate intrusive exposed to the north of Pirentepe at approximately 480700 E 4423000 N.

Photo 7 Selected drill core section from PD-01 (52.80 m to 56.80 m) comprising pyritised andesitic tuffs. The interval from 55.70 m to 56.80 m assayed 1.10 m at 3.15 g/t gold and 40 g/t silver.

Appendix 5 Halilağa photographs

Photo 8 View to the NW showing Pirentepe in the middle distance and Kirazlı on the skyline. In the foreground is the distinctive vegetation anomaly to the north of the quartz porphyry of the Central Zone.

Photo 9 Sheeted and cross cutting quartz veins within quartz porphyry of the Central Zone

Photo 10 Goethite-hematite matrix breccias cross cutting sheeted and stockwork veined quartz porphyry in the Central Zone. The breccia clasts consist of wall rock and are monolithic. The late breccias are interpreted to be related to late extensional faulting.

Photo 11 Quartz-alunite altered dacite with late stage hematite-limonite veining from SE of Kunk Tepe.

Photo 12 Monolithic clast supported matrix breccia with silicified fine grained tuff clasts in an iron rich matrix composed largely of hematite and limonite. Similar breccias were anomalous in gold at Pirentepe.

Photo 13 Well developed crackle breccia with 0.5 cm wide hematite matrix fill including small clasts of broken wall rock. Previous samples from this area produced anomalous gold and is interpreted to be within a zone of early silicification as a result of an upflow zone, which later was brittily deformed allowing circulation of oxidising surface waters.

Photo 14 View of the Central Zone vegetation anomaly developed as a result of near surface leaching and geochemical anomalism. Hole HD-01 is collared on the surface oxidised quartz porphyry in the centre right of the photo.

Photo 15 Detail of drilling rig on site HD-01 and landscape of the Central Zone.

Photo 16 Representative drill core from HD-01 at 120.m depth, sericite-magnetite altered intermediate felsic (feldspar-quartz) porphyry with 7% magnetite, 8% quartz stockwork, 2% pyrite, 0.5% chalcopyrite. 119.90 m to 121.0 m assayed 0.248 ppm Au and 2440 ppm Cu.

Appendix 6 Glossary of Terms

(After Sinclair Knight Mertz unpublished glossary of terms and definitions)

ALTERATION ASSEMBLAGES

Argillic: Clay-rich assemblages dominated by low-temperature clays such as kaolinite, smectite, and interlayered illite-smectite. These are formed by low temperature (<230°C), acid to neutral, low salinity hydrothermal fluids.

Phyllic: Dominated by illite or sericite and quartz, together with pyrite and possibly anhydrite. May also contain minor chlorite, calcite, titanite and rutile. Formed in the presence of moderate to high temperature (approx. 230-400°C), acid to neutral fluids at a range of salinities, commonly in permeable zones and adjacent to veins.

Propylitic: Characterised by chlorite, with some of illite/sericite, epidote, quartz, albite, calcite, and anhydrite. Formed at moderate temperatures (mostly 200-300°C), in the presence of near-neutral pH fluids with a range of salinities, commonly in low permeability areas.

High-temperature propylitic: Contains secondary actinolite and/or garnet in addition to the above assemblage. Forms under similar conditions, but higher temperatures (>290°C) than propylitic assemblages.

Potassic: Major secondary minerals are biotite, orthoclase, quartz, and magnetite. Anhydrite is a common accessory, and minor albite and titanite or rutile can also develop. Potassic alteration is caused by near-intrusive, hot fluids (>300°C) with a strong magmatic character and high salinity.

Advanced argillic: Contains alunite, diaspore, and/or pyrophyllite, together with one or more of quartz, chalcedony, kaolinite, and dickite. These assemblages occur as tabular near-vertical zones formed from condensed acid magmatic vapours in the porphyry environment, and as near horizontal blankets at shallow epithermal levels, where acid-sulphate fluids form from oxidised steam condensates.

Skarn: May contain garnet, clinopyroxene, vesuvianite, scapolite, wollastonite, epidote, amphibole, magnetite and calcite as major components. Minor amounts of biotite, K-feldspar, quartz and chlorite may also be present. Minerals present are similar to those found in potassic, high temperature propylitic and propylitic assemblages of porphyry systems. Developed in the presence of calcium-rich, high salinity fluids over a wide temperature range with early anhydrous minerals forming in the range 300 - 700°C. Occurs near the contact between calcareous lithologies and intrusives.

MINERALISATION

High-sulphidation: Originally referred to opaque minerals which contain sulphur in a high oxidation state, but now used in a broader sense for deposits which contain them; for example “enargite-gold” (or quartz-alunite, or acid sulphate) systems, in which the mineralising hydrothermal fluids have a major magmatic component, and produce acid alteration, with base metal mineralisation at shallow levels.

Hypogene: Formed by processes occurring within the earth, especially mineralisation associated with ascending hot fluids.

Hypothermal: Mineralisation associated with high temperature hydrothermal fluids; originally defined as forming at 300-500°C, today it commonly applies to temperatures over about 500°C.

Low-sulphidation: Originally referred to opaque minerals containing sulphur in a low oxidation state, but now used in a broader sense for the deposits which contain them; for example “adularia-sericite” type systems in which meteoric-dominated fluids produce phyllic, propylitic, and argillic alteration zones.

Mesothermal: Mineralisation produced at deep levels in the crust, from high temperature hydrothermal fluids (250-400°C+), at near lithostatic pressures. The fluids can be meteoric and/or magmatic and/or metamorphic in origin; where the latter is significant; this mineralisation is normally termed metamorphogenic.

Porphyry: Hypothermal deposits occurring as stockworks or disseminations intimately associated with porphyritic intrusives, with mineralisation associated with potassic alteration, although this is frequently overprinted.

Skarn: Mineralisation associated with moderate to high temperature, hydrothermally altered/metasomatised rocks near the contact between intrusive bodies and carbonate rocks.

Supergene: Formed by surficial processes, particularly oxidation, hydration, solution, and deposition.

GENERAL DESCRIPTIVE TERMS

Vein: Material which was chemically deposited by fluids within a rock fracture. Veins exhibit a range of textures and minerals, depending primarily on the temperature, depth, and composition of both the fluid and the host rock. Veins may contain a small amount (<10%) of entrained host rock and/or vein clasts.

Breccia: Coarse (usually >2 mm) fragmental rock, consisting of generally angular clasts of one or more lithologies. A complexly veined rock can have a brecciated appearance (if veins are multi-generational and/or branching), but it is important to differentiate between the two. Veins are generally linear or sinuous, whereas a breccia matrix is highly irregular.

TEXTURAL TERMS FOR VEINS AND BRECCIAS

Matrix: The interstitial material between clasts in a breccia, of which there are two main types. Some breccias may contain a proportion of both types:

Vug (druse): Open cavity within a rock, usually in a vein or breccia cement, which is lined by euhedral prismatic crystals that project into the cavity. **Pseudomorph:** A mineral or minerals occurring in the crystal form of another, usually due to alteration or replacement of the original mineral (e.g. limonite after pyrite, alunite + pyrophyllite after feldspar, quartz after calcite). **Prismatic:** Crystals which exhibit elongate euhedral shapes and have prismatic terminations are common in veins and cements, where they are considered to form by slow crystallisation. Prismatic crystals may be zoned by bands of different composition (e.g. amethyst bands in quartz) or with abundant fluid inclusions.

Colloform: A botryoidal type of texture commonly observed in vein chalcedony, where radiating aggregates of chalcedony have a grape-like outer surface. Banding within this material produces agate.

Comb: Masses of parallel long, thin crystals growing inwards from the vein margins produce a texture like that of a comb.

Saccharoidal: Granular aggregates of equant crystals having the appearance of sugar in hand specimen.

Crustiform: Banding texture produced by differences of mineralogy, texture, and/or colour away from the vein margins. Crustiform banding is commonly produced by alternating chalcedony and saccharoidal quartz layers.

Cockade: Concentric crustiform banding in the cement surrounding matrix supported breccia clasts.

Imbrication: A fabric found within some breccias where there is a subparallel alignment of clasts, similar to that observed within some fluvial gravels.

Vein breccia: Rock consisting predominantly of vein fragments (<10% host rock clasts) in a chemically-deposited matrix. Clasts are generally subangular, and matrix-supported in a matrix of generally similar vein minerals (e.g. quartz, chalcedony), which may be banded and enclose open cavities.

Polymict vein breccia: Rock consisting of altered host rock \pm vein clasts in a chemically deposited matrix, where the matrix, rock, and vein clasts each comprise at least 10% of the rock volume. Clasts are generally subangular, and enclosed by a matrix of vein minerals (e.g. quartz, chalcedony).

Polymict breccia: Rock consisting of various altered host rock \pm lesser (<10%) vein clasts. These may occur in a chemically-deposited matrix, or in a clastic matrix. Clasts range from subangular to subrounded, and may be either clast or matrix-supported.

Monomict breccia: Similar to a polymict breccia, but containing only a single clast type. Jigsaw breccias and crackle breccias are special types of monomict breccia.

Brecciated rock: A rock which consists largely (>90%) of fragments of a single lithology. Clasts are commonly angular, and are usually surrounded by matrix material.

Brecciated vein: Similar to a brecciated rock, but consisting largely (>90%) of vein clasts.

Matrix breccia: A breccia which consists largely (>80%) of clastic matrix material.
Crackle breccia: A type of brecciated rock that has been fractured, but with little or no matrix material. Clasts are still essentially in place. These have been called hydrofractured breccias, but “crackle breccia” is preferred.
Jigsaw breccia: A type of brecciated rock that has been fractured, and has minor matrix material separating clasts. There has been minimal transport and rotation of the clasts, which can be visually fitted together by removal of the matrix.

GENETIC TERMS FOR BRECCIAS

Hydrothermal breccia: A general term for breccias that formed primarily as a result of hydrothermal activity, including phreatic and magmatic-phreatic breccias.

These range from brecciated rocks to vein breccias and polymict breccias, and include both erupted (Hydrothermal eruption breccias) and subsurface rocks. Diagnostic features include the presence of altered host rock clasts, hydrothermal vein clasts, and hydrothermal minerals within the matrix cement, though not all will exhibit all of these features. Plant fragments may occur in hydrothermal eruption breccias.

Phreatic breccia: A more specific term for breccias which form due to the expansion of steam and gas in a water-dominated hydrothermal fluid where there is no direct association of brecciation with magmatic activity. **Magmatic-phreatic breccia:** A specific term for breccias formed due to flashing of hydrothermal fluids following intrusion of magma, but which do not contain juvenile magmatic material.

Phreatomagmatic (diatreme) breccia: A breccia formed by the explosive interaction of magma and groundwater. Diatremes are near-vertical pipe-like bodies up to 1 km across. The breccias are generally polymict, with rounded, matrix supported clasts. The matrix contains finely ground wallrock clasts and juvenile magmatic material, but lacks chemically deposited minerals (unless deposited later).

Tectonic breccia: Breccia formed by the mechanical disruption of rocks in response to tectonic stress. These generally occur in identifiable fault planes, which are commonly steeply dipping. They typically exhibit a planar fabric, imbrication, slickensides, and strain textures such as undulose extinction in quartz crystals.

Volcaniclastic breccia: Breccia formed at or near the surface due to fragmentation on release of magmatic volatiles to produce deposits which include vent breccias, crumble breccias, flow breccias, tuffs, lapilli tuffs, ignimbrites, and lahar deposits. Clasts are mostly unaltered volcanic material in a matrix of fine volcanic detritus.

Appendix 7 Sampling Protocol

The following protocol outlines the procedure that will be applied to sampling drill core at the Pirentepe and Halilağa Exploration Projects. The geologist in charge of logging and/or geotechnical assistant will be responsible for adhering to the following protocol:

Pre-logging

- inspection of core boxes, for missing boxes and footage errors
- digital photography of all boxes
- RQD and core loss

Logging

- Engineering Comments on the competency of core are taken and recorded on the logs
- Fracture analyses with quantitative measuring of all fractures is not being estimated at the moment, but fractures containing gouge material, veins and dominant fracture patterns are measured.

Sampling

- Standardized sample booklets will be utilized at all times. All booklets will be marked up, prior to use, with the standards, blanks and duplicates clearly defined.
- Standards and blanks will both be entered every 20th sample. Duplicate samples (1/4 core), will be entered into the sample flow, at the discretion of the geologist, every 20 samples.
- All holes are sampled from top to bottom of the hole, with most samples averaging one meter or less, unless in unmineralized core where samples are taken every 1.5m.
- For each sample interval, all required parts ('From-To') of the standard sample card are filled in and half of the sample number tag is placed at the starting point of the sample interval in the core box.
- The second half of the tag is put into the sample bag (labelled on both sides with the sample number) by the splitter when he is taking the sample.

Marking Core

- The beginning of a sample will be clearly marked with a black marker, by a line perpendicular to the core
- The sample tag will be placed at the beginning of the sample.

Double-Check

- It will be the geologists' job to double-check on the samples once they are cut and verify that all of the samples collected are properly labelled, with the sample tags inside of the sample bags.

Specific Gravity Measurements

- Specific gravity samples are taken from split core approximately every meter or less when there are changes in lithology or alteration, after the logging and sampling is completed.
- Each sample is a minimum of 5 cm long and up to 25 cm
- The samples are dried in a 105°C oven for 16 hours, then allowed to cool to room temperature.
- The sample is then weighted dry on a scale with 1 gram accuracy
- For the wet sample weight, the sample is first submerged in water for 10-20 minutes to fill all the vugs with water. It is then lowered into the weighting apparatus in a harness into the water bucket for the wet weight.
- The volume of the sample is calculated as: $\text{volume} = \text{mass in air} - \text{mass in water}$
- The specific density is calculated as: $\text{specific density} = \text{mass in air} / \text{volume}$

At the Pirentepe and Halilağa projects, inserting of “blind” quality control samples takes place in the core shack before samples are shipped to the lab. These samples inserted on a routine basis and are used to check laboratory quality and cleanliness. At the beginning of sampling, sample tags are pre-marked with locations for standards, duplicates and blanks before logging.

QA/QC Sampling

- Duplicate samples are taken every 20 samples within the sample series. Duplicate samples are used to monitor sample batches for potential mix-ups and monitor the data variability as a function of both laboratory error and sample homogeneity. The duplicate samples are ¼ split cores done on site before the sample leaves camp.
- Blanks: non-mineralized limestone material was used as a blank, where material was collected from an outcrop in camp, broken with a hammer and inserted into the sample series every 20 samples.
- Standards: Standards are used to test the accuracy of the assays, and to monitor the consistency of the laboratory. They are needed for documentation at the time of ore reserve calculations. Standards were bought from CDN Resource Laboratories Ltd. These standards were randomly inserted into the sample sequences every 20 samples.
- Check Samples: 5% of all assayed sample pulps are being sent to a second laboratory for analysis. This approach identifies variations in analytical procedures between laboratories, possible sample mix-ups, and whether substantial biases have been introduced during the course of the project.
- Analyzing Data: Results of the standards and the blanks are checked and reviewed quickly after results are received. Control charts are used to monitor the data and decide immediately whether the results are acceptable.

Appendix 8 Assay Methods and Detections – ALS Chemex Laboratories, Vancouver, B.C., Canada

Gold - Fire Assay Fusion

For fully quantitative total gold contents, the fire assay procedure is still the preferred choice by laboratories all over the world. Typically the samples are mixed with fluxing agents including lead oxide, and fused at high temperature. The lead oxide is reduced to lead, which collects the precious metals. When the fused mixture is cooled, the lead remains at the bottom, while a glass-like slag remains at the top. The precious metals are separated from the lead in a secondary procedure called cupellation. The final technique used to determine the gold and other precious metals contents of the residue can range from a balance (for very high grade samples), to AAS, ICP-AES or ICP-MS.

| Method code | Description | Range (ppm) |
|-------------|--|-------------|
| Au-AA23 | Au by fire assay and AAS. 30 g nominal sample weight. | 0.005 - 10 |

Aqua Regia Digestion

Quantitatively dissolves base metals for the majority of geological materials, and may provide anomaly enhancement in some geological environments. Major rock forming elements and more resistive metals are only partially dissolved.
